7 **Abstract.** High-resolution geochronology is essential to determine the growth-rate of volcanoes, which is one of the key factors  
8 to establish the periodicity of explosive volcanic eruptions. However, there are less high-resolution eruptive histories ( $>10^6$   
9 years) determined for long-lived submarine arc volcanic complexes than for subaerial complexes, since the submarine  
10 volcanoes are far more difficult to observe than subaerial ones. In this study, high-resolution geochronology and major element  
11 data are presented for Milos Volcanic Field (VF) in the South Aegean Volcanic Arc, Greece. The Milos VF has been active  
12 for over 3 Myrs, and the first two million years of its eruptive history occurred in a submarine setting that has emerged above  
13 sea level nowadays. The long submarine volcanic history of the Milos VF makes it an excellent natural laboratory to study the  
14 growth-rate of a long-lived submarine arc volcanic complex. This study reports twenty-one new high-precision  $^{40}\text{Ar}/^{39}\text{Ar}$  ages  
15 and major element compositions for eleven volcanic units of the Milos VF. This allows us to divide the Milos volcanic history  
16 into at least three periods of different long term volumetric volcanic output rate ( $Q_e$ ). Period I ( $\sim 3.3$ - $2.36$  Ma) and III ( $1.48$   
17 Ma-present) have low  $Q_e$  of  $0.9 \pm 0.5 \times 10^{-5} \text{ km}^3.\text{yr}^{-1}$  and  $0.25 \pm 0.05 \times 10^{-5} \text{ km}^3.\text{yr}^{-1}$ , respectively. Period II ( $2.36$  -  $1.48$  Ma) has  
18 a 3-12 times higher  $Q_e$  of  $3.0 \pm 1.7 \times 10^{-5} \text{ km}^3.\text{yr}^{-1}$ . The  $Q_e$  of the Milos VF is 2-3 orders of magnitude lower than the average  
19 for rhyolitic systems and continental arcs. Most of the effusive eruptions of Period II are probably derived from magma  
20 chambers in the upper crust, whereas the more pumiceous units of Period I and III are probably related to lower crustal hot-  
21 zone.

## 22 1 Introduction

23 Short-term eruptive histories and compositional variations of lavas and pyroclastic deposits of many arc volcanic fields are  
24 well established. However, high-resolution eruptive histories that extend back  $> 10^5$ - $10^6$  years have been determined only for  
25 a handful of long-lived subaerial arc volcanic complexes. Some examples are: Mount Adams (Hildreth and Lanphere, 1994),  
26 Tatará-San Pedro (Singer et al., 1997), Santorini (Druitt et al., 1999), Montserrat (Cole et al., 2002), Mount Baker (Hildreth  
27 et al., 2003a), Katmai (Hildreth et al., 2003b), and Ceboruco-San Pedro (Frey et al., 2004). In order to establish the growth  
28 rate of volcanic complexes and to disentangle the processes which are responsible for the eruption, fractionation, storage and  
29 transport of magmas over time, comprehensive geological studies are required. These include detailed field mapping, sampling,  
30 high-resolution geochronology and geochemical analysis. Based on these integrated studies, the growth-rate of volcanoes can  
31 be determined to establish the periodicity of effusive and explosive volcanism.

32 The Milos Volcanic Field (VF) is a long-lived volcanic complex which has been active for over 3 Myrs. The Milos VF erupted  
33 for a significant part of its life below sea level, similar to the other well studied volcanic structures in the eastern Mediterranean  
34 (Fytikas et al., 1986; Stewart and McPhie, 2006). The eruptive history of the Milos VF has been examined with a broad range  
35 of the chronostratigraphic techniques such as K-Ar, U-Pb, fission track,  $^{14}\text{C}$  and biostratigraphy (e.g. Angelier et al., 1977,  
36 Fytikas et al., 1976, 1986, Traineau and Dalabakis, 1989, Matsuda et al., 1999, Stewart and McPhie, 2006, Van Hinsbergen et  
37 al., 2004 and Calvo et al., 2012). However, most of the published ages have been measured using the less precise K-Ar or  
38 fission track methods, and modern, high precision  $^{40}\text{Ar}/^{39}\text{Ar}$  ages for the Milos VF have not been published so far. In this  
39 study, (1) we provide high-precision  $^{40}\text{Ar}/^{39}\text{Ar}$  geochronology of key volcanic units of the Milos VF and (2) refine the

40 stratigraphic framework of the Milos VF with the new high-precision  $^{40}\text{Ar}/^{39}\text{Ar}$  ages and major element composition. (3) We  
41 also quantify and constrain the compositional and volumetric temporal evolution of volcanic products of the Milos VF.

## 42 **1.1 Geological setting**

43 The Milos VF is part of the South Aegean Volcanic Arc (SAVA), an arc which was formed in the eastern Mediterranean by  
44 subduction of the African plate beneath the Aegean microplate (Figure 1, Nicholls, 1971; Spakman et al., 1988; Duermeijer et  
45 al., 2000; Pe-Piper and Piper, 2007; Rontogianni et al., 2011). The present-day Benioff zone is located approximately 90 km  
46 underneath the Milos VF (Hayes et al., 2018). The upper plate is influenced by extensional tectonics (e.g. McKenzie, 1978;  
47 Pe-Piper and Piper, 2013), which is evident on the island of Milos as horst and graben structures (Figure 2).

48 The Milos VF is exposed on the islands of the Milos archipelago: Milos, Antimilos, Kimolos and Polyegos. The focus of this  
49 study is Milos with a surface area of 151 km<sup>2</sup> for the main island. The geology and volcanology of Milos have been extensively  
50 studied in the last 100 years. The first geological map was produced by Sonder (1924). This work was extended by Fytikas et  
51 al. (1976) and Angelier et al. (1977) and subsequent publications by Fytikas (Fytikas, 1989; Fytikas et al., 1986). Interpretations  
52 based on volcanic facies of the complete stratigraphy were made by Stewart and McPhie (Stewart and McPhie, 2003, 2006).  
53 More detailed studies of single volcanic centres (e.g. Bombarda volcano and Fyriplaka complex) were published by Campos  
54 Venuti and Rossi (1996) and Rinaldi et al. (2003). Milos has also been extensively studied for its epithermal gold  
55 mineralization, that has been summarized by Alfieris et al. (2013). Milos was known during the Neolithic period for its export  
56 of high quality obsidian. Today the main export product is kaolinite, that is mined from hydrothermally altered felsic volcanic  
57 units in the centre of the island (e.g. Alfieris et al. 2013).

58 The geology of Milos can be divided into four main units: (1) metamorphic basement, (2) Neogene sedimentary rocks, (3)  
59 volcanic sequences and (4) the alluvial cover. The metamorphic basement crops out at the southwest, south and southeast of  
60 Milos (Figure 3) and is also found as lithic blocks in many volcanic units. The metamorphic rocks include lawsonite-free  
61 jadeite eclogite, lawsonite eclogite, glaucophane schist, quartz-muscovite-chlorite and chlorite-amphibole schist (Fytikas et  
62 al., 1976, 1986; Grasemann et al., 2018; Kornprobst et al., 1979). The exposed units belong to the Cycladic Blueschist Unit  
63 (Lower Cycladic nappe), whereas eclogite pebbles in the green lahar unit (e.g. Fytikas, 1977) are derived from the Upper  
64 Cycladic Nappe (Grasemann et al., 2018).

65 On top of this metamorphic basement Neogene fossiliferous marine sedimentary rocks were deposited (e.g. Van Hinsbergen  
66 et al. 2004). This sedimentary sequence can be divided into a lower unit A and upper unit B that is unconformably overlain by  
67 volcanoclastic sediments (Van Hinsbergen et al., 2004). Unit A is 80 m thick and consists of fluvial-lacustrine, brackish and  
68 shallow marine conglomerate, sandstone, dolomite and limestone. Unit B is 25-60 m thick and consists of a sandstone overlain  
69 by a succession of alternating marls and sapropels, suggesting a deeper marine setting (Van Hinsbergen et al., 2004). Five  
70 volcanic ash layers that contain biotite are found in this Neogene sedimentary rock sequence either suggesting that volcanic  
71 eruptions in small volume already occurred in the Milos area, or that these ash layers are derived from larger eruptions of  
72 volcanic centres further away from Milos (van Hinsbergen et al., 2004). Age determinations by bio-magneto- and cyclo-  
73 stratigraphy suggested that deposition of Unit A started at approximately 5 Ma, and that Milos subsided 900 m in 0.6 million  
74 years (Van Hinsbergen et al. 2004) due to extension. This subsidence happened ca 1.0-1.5 Myrs before the onset of the main  
75 phase of Pliocene- recent volcanism on Milos.

76 The Pliocene-recent volcanic sequence of Milos has been subdivided into different units by Angelier et al. (1977) and Fytikas  
77 et al. (1986). In addition, Stewart and McPhie (2006) provided a detailed facies analysis of the different volcanic units. The  
78 subdivision by Angelier et al. (1977) is not constrained well due to their limited amount of age data. The subdivision of volcanic  
79 units by Fytikas et al. (1986) and facies descriptions of Stewart and McPhie (2006) are summarized below. It is important to  
80 note that according to Stewart and McPhie (2006), the five volcanic cycles described by Fytikas et al. (1986) are difficult to  
81 match with existing age data and the continuous progression in volcanic construction (Fig. 4). For example, the first phase of

82 Fytikas et al. (1986), the Basal Pyroclastic Series, contains the large pumice cone-crypto dome volcanoes according to Stewart  
83 and McPhie (2006). Two of these pumice-cone crypto dome volcanoes are much younger and intercalated between the  
84 Complex of Domes and Lava Flows (CDLF) of Fytikas et al. (1986).

85 The first volcanic unit deposited in the Milos area is the Basal Pyroclastic Series (BPS) (Fytikas et al., 1986) or submarine  
86 felsic cryptodome-pumice cone volcanoes (Stewart and McPhie, 2006, Figure 2-4). This unit consist of thickly bedded pumice  
87 breccia with a rhyolitic-dacitic composition. These rhyolites-dacites are aphyric or contain quartz-feldspar±biotite phenocrysts.  
88 Graded sandstone and bioturbated and fossil rich (in-situ bivalve shells) mudstone are intercalated, indicating a marine  
89 environment and a water depth of several hundreds of meters (e.g. Stewart, 2003; Stewart and McPhie, 2006), whereas later  
90 degassed magmas with a similar composition intruded as sills and cryptodomes. The BPS has been strongly affected by  
91 hydrothermal fluids, especially the proximal deposits (e.g. Kiliyas et al., 2001).

92 The second volcanic unit was named the Complex of Domes and Lava Flows (CDLF, Fytikas et al., 1986) and the volcanic  
93 facies of this unit is described as the submarine dacitic and andesitic domes by Stewart and McPhie (2006). This phase of  
94 effusive submarine volcanism was predominantly andesitic/dacitic in composition and produced microcrystalline rocks with  
95 phenocrysts of pyroxene, amphibole, biotite and plagioclase. The eruption centres were mainly located along NNE faults and  
96 formed up to 300 m thick deposits extending over areas of 2.5 to 10 km around the eruption centres. In the north-eastern part  
97 of Milos, an andesitic scoria cone provided scoria lapilli and bombs to deeper water settings. Sandstone intercalated in the  
98 CDLF contains both igneous and metamorphic minerals suggesting input from the basement. Rounded pebbles of rhyolite and  
99 dacite indicate that some of the volcanic deposits were above sea level, or in very shallow, near shore environments (e.g.  
100 Stewart and McPhie, 2006).

101 The third volcanic unit is called the Pyroclastic Series and Lava Domes (PSLD) by Fytikas et al. (1986) and belongs to  
102 submarine-to-subaerial dacitic and andesitic lava domes of Stewart and McPhie (2006). This highly variable group is  
103 dominated by rhyolitic, dacitic and andesitic lavas, domes, pyroclastic deposits and felsic pumiceous sediments (Stewart and  
104 McPhie, 2006). Thickness varies between 50-200 m, and the deposits are located in the eastern and northern parts of Milos  
105 (Figure 2 and 3). The initial pyroclastic layers were subaqueously deposited and the extrusion of a dome resulted in deposition  
106 of talus around the margins by mass flow. On top of the dome sand- and siltstone with fossils (*Ostrea* fossil assemblage) and  
107 traction-current structures suggest that the top of the dome was above wave base. The youngest deposits of this unit are dacitic  
108 and andesitic lavas and domes. These domes generated subaerial block-and-ash flow and surge deposits. Paleosols within these  
109 deposits are a clear indicator that some areas were above sea level. The last unit of the PSLD is represented by large subaerial  
110 rhyolitic lava that contain quartz and biotite phenocrysts and is found near Halepa in the south-central part of Milos.

111 The fourth unit consists of the subaerially constructed rhyolitic Complexes of Trachilas and Fyriplaka (CTF) (Fytikas et al.,  
112 1986), which Stewart and McPhie (2006) interpreted as subaerial rhyolitic lava-pumice cones. These two volcanic complexes  
113 are built from rhyolitic pumice deposits and lavas that contain quartz and biotite phenocrysts (10-20 modal %). The deposits  
114 have a maximum thickness of 120 m and decrease to several meters thickness in the distal parts. Basement-derived schist is  
115 found as lithic clasts (Fytikas et al., 1986). In addition, the Kalamos rhyolitic lava dome that outcrops on the southern coast of  
116 Milos produced a lava that spread westwards to the Fyriplaka beach (Figure 2). This lava belongs to this fourth phase and is  
117 probably derived from an older volcano and not the Fyriplaka complex (Campos Venuti and Rossi, 1996).

118 The fifth volcanic unit comprises deposits from phreatic activity, especially in the northern part of the Zefiria Graben and near  
119 Agia Kiriaki (Figure 2 of Stewart and McPhie, 2006). Many overlapping craters are surrounded by lithic breccias that are  
120 composed of variably altered metamorphic basement clasts and volcanic clasts. This phreatic activity has continued into  
121 historic times (Trainau and Dalabakis, 1989). Fytikas et al. (1986) described this unit as “green lahar”, although indicated that  
122 this deposit is not a lahar but the product of phreatic eruptions in the last 0.2 Ma.

## 123 1.2 Previous geochronological studies

124 Previous geochronological work is summarised in Table 1. Angelier et al. (1977) reported six K-Ar ages (0.95-2.50 Ma). These  
125 ages were used in combination with field observations to divide the Milos volcanic succession into four units. However, the  
126 samples from Fyriplaka, the fourth unit, were too young to be dated by Angelier et al. (1977). Fytikas et al. (1976, 1986)  
127 published 16 K-Ar ages for Milos (0.09-3.50 Ma) including an age of 0.09-0.14 Ma for the Fyriplaka complex. Fytikas et al.  
128 (1986) also obtained 3 K-Ar ages for Antimilos ( $0.32 \pm 0.05$  Ma), Kimolos ( $3.34 \pm 0.06$  Ma) and Polyegos ( $2.34 \pm 0.17$  Ma).  
129 Trainau and Dalabakis (1989) dated the very young phreatic deposits by  $^{14}\text{C}$  dating and found ages between 200 BC and 200  
130 AD. Matsuda et al. (1999) published two K-Ar ages of  $0.8 \pm 0.1$  (MI-1) and  $1.2 \pm 0.1$  Ma (MI-4) for the Plakes dome that was  
131 also studied by Fytikas et al. (1986). Bigazzi and Radi (1981) published two fission track ages of  $1.54 \pm 0.18$  and  $1.57 \pm 0.15$   
132 Ma for obsidians of Bombarda-Adamas and Demenaghaki, respectively. Later fission track studies by Arias et al. (2006) ( $1.57$   
133  $\pm 0.12$  and  $1.60 \pm 0.06$  Ma) confirmed these ages. The fission track ages are younger than the K-Ar ages given by Angelier et  
134 al. (1977;  $1.84 \pm 0.08$  Ma for Demenaghaki) and Fytikas et al. (1986;  $1.71 \pm 0.05$  Ma for Bombarda). In the most recent  
135 geochronological study of the Milos VF, Stewart and McPhie (2006) published 4 SHRIMP U/Pb zircon ages: Triades dacite  
136 facies ( $1.44 \pm 0.08$  and  $2.18 \pm 0.09$  Ma), Kalogeros cryptodome ( $2.70 \pm 0.04$  Ma) and the Fylakopi Pumice Breccia ( $2.66 \pm$   
137  $0.07$  Ma). All uncertainties reported here are 1 standard deviation uncertainties as reported in the original publications, except  
138 for the  $^{14}\text{C}$  ages for which uncertainties were not specified.

## 139 2 Methods

### 140 2.1 Mineral separation and sample preparation

141 Samples were collected from all major volcanic units on Milos island as based on the studies of Fytikas et al. (1986), Stewart  
142 and McPhie (2006) and our own observations in the field. Photos of the sample locations and thin sections can be found in the  
143 supplementary material I. Approximately 2 kg of fresh juvenile pyroclastic material or lava was sampled from each unit.  
144 Samples were cut in  $\sim 5$  cm<sup>3</sup> cubes using a diamond saw to remove potentially altered surfaces and obtain the fresh interior  
145 parts. These cubes were ultra-sonicated for 30 minutes in demi-water to remove dust and seawater and dried in an oven  
146 overnight at 50 °C. Dry sample cubes were crushed in a steel jaw crusher, and this fraction was split into two portions of  
147 roughly equal size. One of them was powdered in an agate shatter box and agate ball mill to a grain size of less than 2  $\mu\text{m}$  for  
148 the major-element analysis. The second fraction was sieved to obtain a grain size of 250-500  $\mu\text{m}$  for  $^{40}\text{Ar}/^{39}\text{Ar}$  dating.  
149 Heavy liquids density separation techniques (IJlst, 1973) were used to purify mineral separates (groundmass, biotite, amphibole)  
150 required for the  $^{40}\text{Ar}/^{39}\text{Ar}$  dating. Different densities of heavy liquids were used to obtain groundmass ( $2700 \leq \rho \leq 3000$  kg.m<sup>-3</sup>),  
151 biotite ( $2900 \leq \rho \leq 3100$  kg.m<sup>-3</sup>) and/or amphibole ( $\sim 3100 \leq \rho \leq 3200$  kg.m<sup>-3</sup>). A Franz Isodynamic Magnet separator was  
152 used to remove the magnetic minerals from the non-magnetic minerals and groundmass. The samples for  $^{40}\text{Ar}/^{39}\text{Ar}$  analysis  
153 were purified by handpicking under a binocular optical microscope to select mineral grains without visible alteration and  
154 inclusions.

### 155 2.2 $^{40}\text{Ar}/^{39}\text{Ar}$ dating

156 The mineral and groundmass samples were wrapped in either 6- or 9-mm aluminium foil and packed in 20 mm aluminium  
157 cups, that were vertically stacked. Based on stratigraphy and previous geochronological constraints  $>1$  Ma samples and the  $<1$   
158 Ma samples were irradiated for respectively 7 and 1 hours in irradiation batches VU108 and VU110 in the CLICIT facility of  
159 the OSU TRIGA reactor. The neutron flux for all irradiations was monitored by standard bracketing using the Drachenfels  
160 sanidine (DRA;  $25.52 \pm 0.08$  Ma, modified from Wijbrans et al., 1995 and calibrated relative to Kuiper et al., 2008) and Fish  
161 Canyon Tuff sanidine (FCs;  $28.201 \pm 0.023$  Ma, Kuiper et al., 2008) with Min et al. (2000) decay constants.

162 In total 24 samples (8 groundmasses, 15 biotites and 2 amphiboles, for sample G15M0026 both biotite and amphibole were  
163 analysed) were measured by either  $^{40}\text{Ar}/^{39}\text{Ar}$  fusion and/or incremental heating techniques. For incremental heating  
164 experiments 80-100 grains per sample were loaded into a 25-hole (surface per hole  $\sim 36\text{ mm}^2$ ) copper tray together with single  
165 grain standards in  $\sim 12\text{ mm}^2$  holes. The tray was prebaked in vacuum ( $10^{-5}$ - $10^{-6}$  mbar) at  $250\text{ }^\circ\text{C}$  overnight to remove  
166 atmospheric argon and subsequently baked overnight at  $120\text{ }^\circ\text{C}$  in the ultra-high vacuum sample chamber ( $<5 \times 10^{-9}$  mbar) and  
167 purification system connected to a Thermo Scientific Helix MC mass spectrometer.

168 Samples and standards were heated with a focused laser beam at 8 % power using a 50W CW  $\text{CO}_2$  laser. The released gas was  
169 cleaned by exposure to a cold trap cooled by a Lauda cooler at  $-70\text{ }^\circ\text{C}$ , a SAES NP10 at  $400\text{ }^\circ\text{C}$ , Ti sponge at  $500\text{ }^\circ\text{C}$  and cold  
170 SAES ST172 Fe-V-Zr sintered metal. The five isotopes of argon were measured simultaneously on five different collectors:  
171  $^{40}\text{Ar}$  on the H2-Faraday,  $^{39}\text{Ar}$  on the H1-Faraday or the H1-CDD,  $^{38}\text{Ar}$  on the AX-CDD,  $^{37}\text{Ar}$  on the L1-CDD and  $^{36}\text{Ar}$  on the  
172 L2-CDD for 15 cycles with 33 seconds integration time (CDD: compact discrete dynodes). The Faraday cups on H2 and H1  
173 were equipped with  $10^{13}$  Ohm amplifiers. Procedural blanks were measured every 2 or 3 analyses in different sequences, and  
174 air-shots were measured every 8-12 hours to correct the instrumental mass discrimination. Gain between different collectors  
175 was monitored by measuring  $\text{CO}_2$  on mass 44 in dynamic mode on all collectors. Gain was generally stable over periods of  
176 weeks. Note, that because samples, standards and air calibration runs are measured during the same period, gain correction  
177 does not substantially change the final age results. The raw mass spectrometer data output was converted by an in-house  
178 designed Excel macro script to be compatible with the ArArCalc 2.5 data reduction software (Koppers, 2002). The atmospheric  
179 air value of 298.56 from Lee et al. (2006) is used in the calculations. The correction factors for neutron interference reactions  
180 are  $(2.64 \pm 0.02) \times 10^{-4}$  for  $(^{36}\text{Ar}/^{37}\text{Ar})_{\text{Ca}}$ ,  $(6.73 \pm 0.04) \times 10^{-4}$  for  $(^{39}\text{Ar}/^{37}\text{Ar})_{\text{Ca}}$ ,  $(1.21 \pm 0.003) \times 10^{-2}$  for  $(^{38}\text{Ar}/^{39}\text{Ar})_{\text{K}}$  and  $(8.6 \pm$   
181  $0.7) \times 10^{-4}$  for  $(^{40}\text{Ar}/^{39}\text{Ar})_{\text{K}}$ . All uncertainties are quoted at the  $1\sigma$  level and include all analytical errors (i.e. blank, mass  
182 discrimination and neutron interference correction and analytical error in J-factor, the parameter associated with the irradiation  
183 process).

184 A reliable plateau age is defined as experiments with at least 3 consecutive steps overlapping at 2-sigma, containing  $>50\%$  of  
185 the  $^{39}\text{Ar}_{\text{K}}$ , a Mean Square Weighted Deviate (MSWD) value  $<2.5$ , and with an  $^{40}\text{Ar}/^{36}\text{Ar}$  inverse isochron intercept that does  
186 not deviate from atmospheric argon at 2-sigma. All the inverse isochron ages used the same steps as used in the weighted mean  
187 ages, and all relevant analytical data for the age calculations following standard practices (Schaen et al., 2020) can be found  
188 in in the supplementary material II.

### 189 **2.3 Whole-rock major element analysis by XRF**

190 Major-element concentrations were measured by X-ray fluorescence spectroscopy (XRF) on a Panalytical AxiosMax. A  
191 Panalytical Eagon2 was used to create 40mm fused glass beads of  $\text{Li}_2\text{B}_4\text{O}_7/\text{LiBO}_2$  (65.5:33.5%, Johnson & Johnson  
192 Spectroflux 110) with a 1:6 dilution sample-flux ratio that were molten at  $1150\text{ }^\circ\text{C}$ . Sample powders were ignited at  $1000\text{ }^\circ\text{C}$   
193 for 2 hours to determine loss on ignition (LOI) before being mixed with the  $\text{Li}_2\text{B}_4\text{O}_7/\text{LiBO}_2$  flux. Interference corrected spectra  
194 intensities were converted to oxide-concentrations against a calibration curve consisting of 30 international standards. The  
195 precision, expressed as the coefficient of variation (CV), is better than 0.5%. The accuracy, as measured on the international  
196 standards AGV-2, BHVO-2, BCR-2 and GSP-2 was better than 0.7% (1 RSD) (supplementary material III).

### 197 **2.4 Rock textural analysis and eruption volume calculations**

198 The crystallinity and vesicularity were estimated with Image-J software by scanning the thin section of each sample 4-6 times  
199 to cover the entire area. For the crystallinity only the phenocrysts were considered, crystals smaller than  $50\text{ }\mu\text{m}$  were included  
200 in the groundmass. The estimations of crystallinity and vesicularity on the older samples ( $>1.0\text{ Ma}$ ) of Milos VF are all from  
201 lava and domes. The younger samples ( $<1.0\text{ Ma}$ ) are from pumiceous pyroclastic units. The other old pumices of the Profitis  
202 Illias and Filakopi volcanoes are not included in this study due to the severe alteration that prevents the collection of reliable

203 geochemical and geochronological data on these samples. The mean value and standard deviation of the crystallinity and  
204 vesicularity were also calculated.  
205 The minimum and/or maximum eruption volume of each volcano during each eruption period is derived from the ranges of  
206 thickness and surface areas that are reported in Campos and Rossi (1996) and Stewart and McPhie (2006). We converted these  
207 volumes to Dense Rock Equivalent (DRE) based on the magma type of different deposits. This analysis only includes the  
208 onshore deposits and results in a smaller estimate for larger pyroclastic volumes. The DRE volume is calculated using the  
209 equation of (Croweller et al., 2012):

$$210 \quad DRE (km^3) = \frac{tephra \text{ vol } (km^3) \times tephra \text{ density } (kg/m^3)}{magma \text{ density } (kg/m^3)}$$

211 Tephra density is assumed to be 1000 kg/m<sup>3</sup> (Croweller et al., 2012). Magma density varies depending on the magma type.  
212 Here we used 2300 kg/m<sup>3</sup> for rocks with a SiO<sub>2</sub> range of 65-77 wt.% and 2500 kg/m<sup>3</sup> for all samples with SiO<sub>2</sub> < 65 wt.%  
213 (Table 4 for major-element composition). DRE corresponds to the unvesiculated erupted magma volume and DRE volumes  
214 are converted to include vesicularity. Therefore, we did not convert the volume of some cryptodome and lavas from Profitis  
215 Ilias (G15M0017), Triades (G15M0021-24), Dhemeneghaki (G15M0032B) and Halepa (G15M0013) to the DRE since they  
216 contain less than 5% vesicles.

## 217 **3 Results**

### 218 **3.1 <sup>40</sup>Ar/<sup>39</sup>Ar age results**

219 In this section, we present our groundmass, biotite and amphibole <sup>40</sup>Ar/<sup>39</sup>Ar results for eleven volcanic units of Milos. The  
220 <sup>40</sup>Ar/<sup>39</sup>Ar ages range from 0.06 to 4.10 Ma and cover most of the major volcanic units of Milos. Table 2 and 3 show the  
221 <sup>40</sup>Ar/<sup>39</sup>Ar results of incremental heating steps and single grain fusion analyses, respectively. Note that the Irr-ID column in  
222 these two Tables represents the irradiation ID of the analytical experiment (e.g. VU108-, VU110-) and the top right superscripts  
223 (G, B, A, O) in the sample IDs (e.g., G15M0029<sup>G</sup>, G15M0021<sup>B</sup>) refer to groundmass, biotite, amphibole and obsidian.

#### 224 **3.1.1 Groundmass <sup>40</sup>Ar/<sup>39</sup>Ar plateau and/or isochron ages**

225 All groundmass samples yielding <sup>40</sup>Ar/<sup>39</sup>Ar plateau and isochron ages with more than 50% <sup>39</sup>Ar<sub>K</sub> and less than 2.5 MSWD  
226 included in their age spectrum are shown in Figure 4 and reported in Table 2. The <sup>40</sup>Ar/<sup>36</sup>Ar isochron intercepts do not deviate  
227 from atmospheric argon at the 2-sigma level, unless stated otherwise (Table 3). Sample G15M0016 was collected from a dyke  
228 at Kleftiko in the southwest of Milos (Figure 2). Three incremental heating experiments were performed on the groundmass  
229 of this sample (Figure 5A). The first experiment (VU108-Z8a) produced a weighted mean age of 2.71 ± 0.02 Ma (MSWD  
230 2.31; <sup>39</sup>Ar<sub>K</sub> 79.6%; inverse isochron age 2.65 ± 0.10 Ma). The other two, VU108-Z8a\_4 and VU108-Z8b\_1, have plateau ages  
231 of 2.61 ± 0.03 Ma (MSWD 0.93; <sup>39</sup>Ar<sub>K</sub> 57.4%; inverse isochron age 2.69 ± 0.10 Ma) and 2.67 ± 0.01 Ma (MSWD 1.50; <sup>39</sup>Ar<sub>K</sub>  
232 65.57%; inverse isochron age 2.55 ± 0.05 Ma), respectively. The three experiments are remarkably similar. Although the  
233 amount of radiogenic <sup>40</sup>Ar is low (<20%), a combined age of 2.66 ± 0.01 Ma is considered to be best estimate with a relatively  
234 high MSWD value (2.51).

235 Two lava samples, G15M0019 and G15M0020, were collected from Kontaro in north-eastern Milos (Figure 2). Three replicate  
236 incremental heating steps experiments of groundmass from sample G15M0019 (VU108-Z6a\_4; VU108-Z6a\_5 and VU108-  
237 Z6b\_1, Figure 5B) were performed that are not reproducible. Their plateau ages range from 1.55 Ma to 1.62 Ma with relatively  
238 high MSWD (3.8-4.5), 56-95% of the total <sup>39</sup>Ar<sub>K</sub>, 34-53% of radiogenic <sup>40</sup>Ar, 0.88-1.02 of K/Ca and an atmospheric isochron  
239 intercept of 297-315. We consider the isochron age from the last experiment (VU108-Z6b\_1) as the only reliable age (1.48 ±  
240 0.02 Ma, MSWD 0.44) because of the least scatter in this experiment, and therefore the best estimate for the eruption age.  
241 Three replicate incremental heating steps experiments of groundmass from sample G15M0020 (VU108-Z5a\_5; VU108-Z5b\_1

242 and VU108-Z5b\_2, Figure 5C) were analysed. These experiments are similar at the lower temperature heating steps. They  
243 produced statistically meaningful plateau ages ranging from 1.52-1.56 Ma with 41-62% of the total  $^{39}\text{Ar}_K$ , 18-48% of  
244 radiogenic  $^{40}\text{Ar}$ , 1.51-1.73 of K/Ca and an atmospheric isochron intercept of 295-300. Their combined weighted mean age is  
245  $1.54 \pm 0.01$  Ma (MSWD 3.06;  $^{39}\text{Ar}_K$  57.32%) with 25.31% of  $^{40}\text{Ar}^*$ .

246 Sample G15M0032B (obsidian) was collected from a pumice cone volcano at Demeneghaki (Figure 2). One incremental  
247 heating experiment of this sample (VU108-Z18, Figure 5D) yielded a plateau age of  $1.825 \pm 0.002$  Ma (MSWD 0.91;  $^{39}\text{Ar}_K$   
248 98.6%). The  $^{40}\text{Ar}^*$  is 93.86%. The inverse isochron age is identical to the weighted mean plateau age  $1.825 \pm 0.002$  Ma. The  
249 age of  $1.825 \pm 0.002$  Ma is considered the best estimate for the eruption age of the Demeneghaki obsidian.

### 250 3.1.2 Groundmass $^{40}\text{Ar}/^{39}\text{Ar}$ plateau and/or isochron ages (25-40% $^{39}\text{Ar}_K$ released)

251 The results shown in Figure 5 did not yield weighted mean plateau according to standard criteria including  $^{39}\text{Ar}_K > 50\%$ , but  
252 still provide some useful age information. Sample G15M0017 was collected from a cryptodome of the Profitis Illias volcano  
253 of southwestern Milos (Figure 2). Three replicate incremental heating experiments, VU108-Z7a, VU108-Z7a\_4 and VU108-  
254 Z7b\_1, have been performed on this sample which resulted in disturbed age spectra (Figure 6A). The consecutive lower  
255 temperature steps of all experiments define ages of  $< 2.5$  Ma, which is much younger than the ages of the submarine pyroclastic  
256 products of the lower series at Kleftiko and/or Profitis Illias (3.0-3.5 Ma, Fytikas et al., 1986 and Stewart and McPhie, 2006).  
257 At the consecutive higher temperature heating steps, these experiments yielded  $3.64 \pm 0.08$  Ma ( $^{40}\text{Ar}/^{36}\text{Ar}$   $293.87 \pm 4.77$ ;  
258 VU108-Z7a),  $4.10 \pm 0.06$  Ma ( $^{40}\text{Ar}/^{36}\text{Ar}$   $298.44 \pm 15.51$ ; VU108-Z7a\_4) and  $3.41 \pm 0.05$  Ma ( $^{40}\text{Ar}/^{36}\text{Ar}$   $295.97 \pm 7.34$ ; VU108-  
259 Z7b\_1). The total fusion and inverse isochron ages of the three experiments gave large ranges of 2.25-3.23 and 3.68-4.14 Ma,  
260 respectively, and none of these high temperature heating steps produced a statistical plateau (all MSWD  $> 2.0$ ). The amount  
261 of radiogenic  $^{40}\text{Ar}$  of both  $^{40}\text{Ar}/^{39}\text{Ar}$  result from our sample and K-Ar from previous studies (Fytikas et al., 1986) is rather low  
262 ( $< 15\%$ ) for a sample of this age based on our laboratory experience. Therefore, the estimated age range for the oldest volcanic  
263 products of the Milos VF should be confirmed by other dating techniques.

264 Sample G15M0015 is also a cryptodome breccia from Profitis Illias (Figure 2). Two replicate incremental step heating  
265 experiments were performed on the groundmass of this sample (VU108-Z9a and VU108-Z9b\_1, Figure 6B). Experiment  
266 VU108-Z9a groundmass shows a disturbed age spectrum with ages increasing from  $\sim 3$  Ma in the initial heating steps to  $\sim 3.2$   
267 Ma followed by a decrease to  $\sim 3$  Ma in the high temperature heating steps. The consecutive heating steps only exist at the  
268 lower temperature steps yielding a “plateau” of  $3.12 \pm 0.02$  Ma (MSWD 9.07). Due to the excess argon ( $^{40}\text{Ar}/^{36}\text{Ar}$   $304.19 \pm$   
269  $1.25$  comprising 43.07% of the released  $^{39}\text{Ar}_K$ ), the inverse isochron of  $3.06 \pm 0.02$  Ma (MSWD 0.01) is more reliable for this  
270 analysis. The inverse isochron age of the second groundmass (VU108-Z9b\_1) is identical at  $3.04 \pm 0.02$  Ma (MSWD 1.14;  
271  $^{39}\text{Ar}_K$  27.00%) and  $^{40}\text{Ar}/^{36}\text{Ar}$  of  $293.83 \pm 1.38$  obtained at high temperature steps. The two experiments are remarkably similar.  
272 Although the sample does not formally fulfil the definition of a plateau age comprising  $> 50\%$   $^{39}\text{Ar}_K$  released, a combined age  
273 of  $3.06 \pm 0.02$  Ma (MSWD 1.14;  $^{39}\text{Ar}_K$  22.79%,  $^{40}\text{Ar}^*$  41.77%) most likely represents the eruption age. This  $^{40}\text{Ar}/^{36}\text{Ar}$  age is  
274 consistent with the K-Ar age from the same lithology of  $3.08 \pm 0.08$  Ma (Fytikas et al. 1986).

275 Sample G15M0029 is an andesite collected from Korakia in the northeast of Milos (Figure 2). Two incremental heating  
276 experiments (VU108-Z16a and VU108-Z16b\_1, Figure 6C) were performed on this sample. The two experiments are  
277 remarkably similar with a decreasing age from  $\sim 2.85$  Ma at the lower temperature heating steps to 2.65 Ma at the higher  
278 temperatures. The higher temperature heating steps of both experiments yielded weighted mean plateau ages of  $2.67 \pm 0.01$   
279 Ma (MSWD 0.96;  $^{39}\text{Ar}_K$  23.61%,  $^{40}\text{Ar}^*$  56.34%; inverse isochron age  $2.68 \pm 0.02$  Ma) and  $2.69 \pm 0.01$  Ma (MSWD 1.32;  
280  $^{39}\text{Ar}_K$  27.08%,  $^{40}\text{Ar}^*$  55.78%; inverse isochron age  $2.67 \pm 0.03$  Ma). The isochron intercepts for both experiments are  
281 atmospheric. The combined age of  $2.68 \pm 0.01$  Ma should be considered with caution due to the rather low amount of released  
282  $^{39}\text{Ar}$  (23-28%).

### 283 3.1.3 Single biotite grain $^{40}\text{Ar}/^{39}\text{Ar}$ fusion and/or isochron ages

284 Results of nine single fusion experiments are given in Figure 7. Nine or ten replicate single fusion experiments were conducted  
285 on 5-10 grains biotite per fusion. Sample G15M0006 is from a solid in-situ dacite with columnar joints from the Kalogeros  
286 cryptodome in the northeast of Milos (VU108-Z11, Figure 7A). The sample shows a weighted mean age of  $2.72 \pm 0.01$  Ma  
287 with 9 out of 10 total fusion experiments (MSWD 1.95; 9/10) with an average 47.9% of radiogenic  $^{40}\text{Ar}$ . The inverse isochron  
288 age is  $2.62 \pm 0.04$  Ma (MSWD 0.99). Note that excess argon ( $^{40}\text{Ar}/^{36}\text{Ar}$  310.2  $\pm$  4.0) is present, hence the inverse isochron age  
289 is younger compared to the weighted mean age. The isochron age of  $2.62 \pm 0.04$  Ma is considered as the best estimate for the  
290 emplacement age.

291 Sample G15M0025 was collected from the Mavros Kavos lava dome located in the west of Milos (Figure 2). The biotite of  
292 this sample (VU108-Z2, Figure 7B) shows a weighted mean age of  $2.36 \pm 0.01$  Ma (MSWD 0.70; 9/10;  $^{40}\text{Ar}^*$  37.60%, inverse  
293 isochron age  $2.34 \pm 0.04$  Ma) with an  $^{40}\text{Ar}/^{36}\text{Ar}$  intercept of  $300.6 \pm 3.5$ . The age of  $2.36 \pm 0.01$  Ma is considered the best  
294 eruption age estimate for this sample.

295 Sample G15M0023 and -24 are from the Triades lava dome of the northeast of Milos (Figure 2). A mafic enclave G15M0022  
296 (host rock G15M0021) was collected from a lava near Cape Vani (Figure 2). The total fusion experiments of the biotites show  
297 that their initial  $^{40}\text{Ar}/^{36}\text{Ar}$  estimates overlap with air (296-300). The total fusion ages gave the best estimates for their eruption  
298 ages of 2.10-2.13 Ma using 22 out of 31 fusions with a range of radiogenic  $^{40}\text{Ar}$  between 30-36% (Figure 7B).

299 Sample G15M0013 is from the rhyolitic Halepa lava dome in the south of Milos (Figure 2). The total fusion experiment  
300 (VU108-Z13, Figure 7C) on biotite of this sample produced a weighted mean age of  $1.04 \pm 0.01$  Ma (MSWD 1.62; 9/10,  $^{40}\text{Ar}^*$   
301 26.3%; inverse isochron age  $1.02 \pm 0.04$  Ma) with an initial  $^{40}\text{Ar}/^{36}\text{Ar}$  estimate of  $299.8 \pm 4.1$ . The best estimate for the  
302 eruption age of the Halepa rhyolite is  $1.04 \pm 0.01$  Ma.

303 Sample G15M0034 and 35 were collected from a lava dome located southeast of the Trachilas cone (Figure 2). Nine total  
304 fusion experiments (VU108-Z21, Figure 7C) were performed on biotite of sample G15M0035 and yielded  $0.63 \pm 0.02$  Ma  
305 (MSWD 1.26; 6/9;  $^{40}\text{Ar}^*$  4.9%; inverse isochron age  $0.77 \pm 0.13$  Ma). The atmospheric isochron intercept overlaps with air at  
306 2-sigma ( $296.4 \pm 1.7$ ). The 4.9% of radiogenic  $^{40}\text{Ar}$  is so low that we should consider the age of  $0.63 \pm 0.02$  Ma with caution.  
307 For biotite of sample G15M0034 (VU108-Z20, Figure 7C) one total fusion experiment produced a weighted mean age of  $0.51$   
308  $\pm 0.02$  Ma (MSWD 0.95; 6/10;  $^{40}\text{Ar}^*$  3.5%; inverse isochron age  $0.61 \pm 0.08$  Ma) with an atmospheric isochron intercept. The  
309 age of  $0.51 \pm 0.02$  Ma also needs to be considered as possibly suspect due to the low amount of radiogenic  $^{40}\text{Ar}$ .

310 Sample G15M0033 was collected from the Kalamos lava along the coast of the southwest of the Fyriplaka rhyolitic complex  
311 (Figure 2). Biotite of this sample (VU108-Z19, Figure 7C) yielded  $0.412 \pm 0.004$  Ma (MSWD 1.10; 8/10; inverse isochron  
312 age  $0.39 \pm 0.02$  Ma) with  $\sim 22.2\%$  of radiogenic  $^{40}\text{Ar}$  which is considered as the eruption age for the Kalamos lava.

### 313 3.1.4 Multiple biotite grain $^{40}\text{Ar}/^{39}\text{Ar}$ incremental heating plateau and/or isochron ages

314 Figure 8 displays the biotite  $^{40}\text{Ar}/^{39}\text{Ar}$  ages measured by the incremental heating steps method. Sample G15M0021 is the host  
315 lava of mafic enclave G15M0022. Twelve replicate total fusion experiments of its biotite (VU110-Z4, Table 3) produced an  
316 age of  $2.48 \pm 0.04$  Ma (MSWD 1.49; 4/12,  $^{40}\text{Ar}^*$  36.09%; inverse isochron age  $3.44 \pm 0.46$  Ma). Although this suggests a  
317 correct age, the large analytical error of each fusion ( $>0.3$  Ma on average) and poor reproducibility (4/12) of this experiment  
318 probably results in an unreliable age. Therefore, two more incremental heating experiments were performed on this sample  
319 (VU110-Z4\_2 and VU110-Z4\_2b, Figure 8A), that gave an age of  $1.97 \pm 0.01$  Ma (MSWD 1.66;  $^{39}\text{Ar}_k$  63.8%,  $^{40}\text{Ar}^*$  54.7%;  
320 inverse isochron age  $1.97 \pm 0.03$  Ma) and  $2.01 \pm 0.01$  Ma (MSWD 6.76;  $^{39}\text{Ar}_k$  75.39%,  $^{40}\text{Ar}^*$  57.84%; inverse isochron age  
321  $2.04 \pm 0.05$  Ma), respectively. The scatter in the latter is too high to define a reliable plateau age and the first incremental  
322 heating experiment is considered as the best estimate of the eruption age of this sample.

323 Sample G15M0007 was collected from the rhyolitic Trachilas complex in the north of Milos (Figure 2). Twenty-two total  
324 fusion (VU110-Z12, Table 3) and two incremental heating experiments (VU110-Z12a and 12b, Figure 8B) were performed

325 on biotite of this sample. The total fusion experiments did not result in a reliable age due to the large errors of single steps ( $\pm$   
326 0.19 Ma on average) and the rather low amount of radiogenic  $^{40}\text{Ar}$  (9.1%). On the other hand, the first incremental heating  
327 experiment produced a plateau age of  $0.30 \pm 0.01$  Ma (MSWD 4.61;  $^{39}\text{Ar}_K$  56.60%; inverse isochron age  $0.28 \pm 0.05$  Ma)  
328 including 14.51% of radiogenic  $^{40}\text{Ar}$ . The second incremental heating experiment yielded a plateau of  $0.317 \pm 0.004$  Ma  
329 (MSWD 1.29;  $^{39}\text{Ar}_K$  74.05%; inverse isochron age  $0.31 \pm 0.03$  Ma) with a higher amount of radiogenic  $^{40}\text{Ar}$  (18.30%). The  
330 isochron intercepts of both incremental heating experiments are atmospheric. The second experiment is the best estimate for  
331 the eruption age, since it contained the largest amount of radiogenic  $^{40}\text{Ar}$  and has a better reproducibility of single heating  
332 steps.

333 Three pumice clasts (G15M0008-9 and G15M0012) were sampled from different layers of the Fyriplaka complex (Figure 2).  
334 The first incremental step heating experiment of biotite from sample G15M0009 (VU110-Z23a, Figure 8C) gave negative ages  
335 at the lower temperature heating steps. Four consecutive higher temperature heating steps seem to define a “plateau” of  $0.11$   
336  $\pm 0.02$  Ma (MSWD 1.37) only using 18.33% of the total  $^{39}\text{Ar}_K$  with 1.65% of radiogenic  $^{40}\text{Ar}$ . The second experiment (VU110-  
337 Z23b) also yielded a “plateau” of  $0.11 \pm 0.03$  Ma (MSWD 6.77) at higher temperature heating steps including 41.05% of the  
338 total  $^{39}\text{Ar}_K$  and 3.13% of radiogenic  $^{40}\text{Ar}$ . The significantly larger error of the isochron age may be due to the clustering of data  
339 close to zero on the y-axis. The two experiments (VU110-Z23a and Z23b) are comparable. The combined age of  $0.11 \pm 0.02$   
340 (MSWD 3.5) is consistent with the age of 0.09-0.14 Ma from Fytikas et al. (1986). Although only 29.50% of the released  $^{39}\text{Ar}_K$   
341 was used for this sample, we believe this age is the eruption age of this layer in the Fyriplaka complex.

342 For biotite of sample G15M0012 both incremental step heating experiments are comparable. Both of them yielded plateau  
343 ages of  $0.05 \pm 0.01$  Ma (VU110-Z24a; MSWD 3.09;  $^{39}\text{Ar}_K$  38.89%,  $^{40}\text{Ar}^*$  2.89%; inverse isochron age  $0.14 \pm 0.03$  Ma) and  
344  $0.09 \pm 0.02$  Ma (VU110-Z24b; MSWD 8.16;  $^{39}\text{Ar}_K$  48.04%,  $^{40}\text{Ar}^*$  4.59%; inverse isochron age  $0.09 \pm 0.05$  Ma) at higher  
345 temperature heating steps (Figure 8C). The clustering of data points of experiment VU110-Z24a could result in the lower  
346 initial estimate of  $^{40}\text{Ar}/^{36}\text{Ar}$  ( $285.98 \pm 4.76$ ). However, the combined age of  $0.07 \pm 0.01$  Ma, using 43.53% of the total  $^{39}\text{Ar}_K$   
347 with an atmospheric isochron intercept ( $295.67 \pm 7.39$ ), could be the representative age of eruption.

348 Biotite of sample G15M0008 did not result in a reliable plateau in the first incremental step heating experiment (VU110-Z22a,  
349 Figure 8C) but shows a very disturbed age spectrum. The second experiment (VU110-Z22b) yielded  $0.062 \pm 0.003$  Ma (MSWD  
350 0.91) using 71.81% of the total  $^{39}\text{Ar}_K$  with 2.69% of radiogenic  $^{40}\text{Ar}$  as the best estimate of the eruption age.

### 351 **3.1.5 Multiple amphibole grain $^{40}\text{Ar}/^{39}\text{Ar}$ multi-grain incremental heating plateau and/or isochron ages**

352 There are only two amphibole samples that yielded  $^{40}\text{Ar}/^{36}\text{Ar}$  plateau and/or isochron ages (Figure 9A and B). Sample  
353 G15M0004 was collected from the pyroclastic series of Adamas from the PSLD (Fytikas et al., 1986), to the north of Bombarda  
354 (Figure 2). Two replicate heating experiments of G15M0004 amphibole (VU108-Z10\_1 and VU108-Z10\_2) were performed  
355 yielding  $2.99 \pm 0.11$  Ma (MSWD 1.00;  $^{39}\text{Ar}_K$  87.31%,  $^{40}\text{Ar}^*$  16.36%; inverse isochron age  $7.89 \pm 2.46$  Ma) and  $2.86 \pm 0.09$   
356 Ma (MSWD 1.50;  $^{39}\text{Ar}_K$  86.18%,  $^{40}\text{Ar}^*$  17.58%; inverse isochron age  $0.70 \pm 0.29$  Ma). The variable atmospheric isochron  
357 intercept of both experiments ( $^{40}\text{Ar}/^{36}\text{Ar}$   $202.39 \pm 48.47$  and  $348.91 \pm 27.33$ ) is due to clustering of the data points. Note that  
358 also the amount of radiogenic  $^{40}\text{Ar}$  is rather low (~17%). The two experiments are remarkably similar. A combined inverse  
359 isochron age of  $1.95 \pm 0.45$  Ma (MSWD 1.17;  $^{40}\text{Ar}/^{36}\text{Ar}$   $319.51 \pm 14.70$ ) is considered the best estimate, but ideally this age  
360 should be checked by other techniques.

361 Sample G15M0026 is from the same location as sample G15M0025, which gives us the opportunity to compare the biotite age  
362 with the amphibole age. One total fusion experiment of biotite (VU108-Z1b) yielded a weighted mean age of  $2.35 \pm 0.01$  Ma  
363 (MSWD 1.36;  $^{40}\text{Ar}^*$  38.6%). The atmospheric isochron intercept is low ( $^{40}\text{Ar}/^{36}\text{Ar}$   $292.01 \pm 2.92$ ), the inverse isochron age of  
364  $2.42 \pm 0.04$  Ma (MSWD 0.93) is considered the best result from the biotite. Two incremental heating experiments for  
365 amphibole (VU108-Z1b\_1 and VU108-Z1b\_2) gave plateau ages of 2.67-2.70 Ma which are much higher values than the  
366 biotite inverse isochron ages (2.28-2.31 Ma). This result could be caused by the high  $^{40}\text{Ar}/^{36}\text{Ar}$  isochron intercepts (>320) with

367 large uncertainties of  $\sim 29$ . Therefore, on the basis of the remarkable similarity of the two experiments, the combined inverse  
368 isochron age of  $2.31 \pm 0.28$  Ma (MSWD 0.93,  $^{39}\text{Ar}_K$  71.36%,  $^{40}\text{Ar}^*$  34.97%) is considered as the best estimate from amphibole  
369 which overlaps with the biotite age of  $2.42 \pm 0.03$  Ma. This biotite age of  $2.42 \pm 0.03$  Ma is considered to the best approximation  
370 of the eruption age.

### 371 **3.2 Major element results**

372 Major-element results are given in Table 4. The major element compositions range from 54 to 78 wt.%  $\text{SiO}_2$  (basaltic-andesite-  
373 rhyolite to dacite-rhyolite, see Figure 10A). The most felsic samples ( $\text{SiO}_2 > 75$  wt.%) belong to the Fyriplaka and Trachilas  
374 complexes. Our data overlap with those of previous studies and display a similar range in  $\text{SiO}_2$ - $\text{K}_2\text{O}$  (Francalanci and Zellmer,  
375 2019 and reference therein). The samples of Polyegos are similar to the Fyriplaka and Trachilas complexes, whereas the older  
376 Milos samples overlap with Kimolos and Antimilos (Fytikas et al., 1986, Francalanci et al., 2007).

377 Although some samples of Antimilos are tholeiitic, all of the Milos volcanic units belong to the calc-alkaline and medium to  
378 high-K series (Figure 10B). A mafic inclusion, sample G15M0022, has high  $\text{K}_2\text{O}$  (6%), similar to sample G15M0021 (7.2  
379 wt.%). Both of them were collected from the Vani Cape area (Fig. 2). The  $\text{SiO}_2$  wt.% versus our  $^{40}\text{Ar}/^{39}\text{Ar}$  ages diagram (Figure  
380 11A) shows that there is a tendency of the volcanic units to become more felsic over time. In the diagram with  $\text{K}_2\text{O}/\text{SiO}_2$   
381 versus age there is no significant change (Figure 11C).

### 382 **3.3 Variations of rock texture and eruption volume with ages**

383 Figure 11D and E show the variations of crystallinity and vesicularity of the studied samples versus the  $^{40}\text{Ar}/^{39}\text{Ar}$  ages. There  
384 is lack of geochemical and petrological data of the pumice deposit of the Profitis Illias ( $> 3.0$  Ma). The other old pumiceous  
385 pyroclastic unit, Filakopi ( $\sim 2.66$  Ma) volcano, has low crystallinity ( $< 10\%$ ) and high vesicularity (10-100%) based on the data  
386 of Stewart (2003). Before 1.48 Ma, the crystallinity of the Milos volcanic units is relatively high (10-40%) and vesicularity  
387 varies between 1-10%. After 1.48 Ma, the lava unit of the Halepa dome and the young pumiceous unit of Trachilas and  
388 Fyriplaka complexes ( $< 1.0$  Ma) have low crystallinity ( $< 10\%$ ), and the high vesicularity (10-100%). The volcanic complex  
389 of Milos was largely ( $\sim 85\%$  by volume) constructed before  $\sim 1.48$  Ma (Figure 11A). During 1.48 Ma-present, only a small  
390 volume ( $\sim 15\%$ ) of rhyolitic magma was added from different eruption vents.

## 391 **4 Discussion**

392 In this section, our  $^{40}\text{Ar}/^{39}\text{Ar}$  results are compared with previously published geochronological data, and subsequently used to  
393 refine the stratigraphy of the Milos VF. In the last part, we will discuss the temporal variations in major elements and the  
394 volumetric volcanic output rate of the Milos VF.

### 395 **4.1 Comparison with the previous geochronological studies on the Milos VF**

396 K-Ar ages may show undesirable and unresolvable scatter due to various problems: (1) in accurate determination of radiogenic  
397 argon due to either incorporation of excess argon or incomplete degassing of argon during the experiments; (2) inclusion of  
398 cumulate or wall rock phenocrysts in bulk analyses; (3) disturbance of a variety of geological processes such as slow cooling,  
399 thermal reheating; (4) unrecognized heterogeneities due to separate measurements of potassium and argon content by different  
400 methods; (5) requirement of relatively large quantities (milligrams) of pure sample (e.g. Lee, 2015). In addition to these  
401 methodological issues, in the case of Milos we observe that hydrothermal alteration caused substantial kaolinitisation, in  
402 particular the felsic volcanic samples, that most likely has affected the K-Ar systematics. Some of these issues are also valid  
403 for the  $^{40}\text{Ar}/^{39}\text{Ar}$  method, however, the K-Ar method does not allow testing if ages are compromised.

404  $^{40}\text{Ar}/^{39}\text{Ar}$  ages only need isotopes of argon to be measured from a single aliquot of sample with the same equipment that can  
405 eliminate some of the problems with sample inhomogeneity. Furthermore, step heating and multiple single fusion experiments  
406 can shed light on sample inhomogeneity due to partial alteration effects. The high sensitivity of modern noble gas mass  
407 spectrometers for  $^{40}\text{Ar}/^{39}\text{Ar}$  measurements results in very small sample amounts needed for analysis, that can yield more  
408 information on the thermal or alteration histories than larger samples. Moreover, other argon isotopes ( $^{36}\text{Ar}$ ,  $^{37}\text{Ar}$  and  $^{38}\text{Ar}$ ) can  
409 be used to infer some information about the chemical compositions (i.e. Ca and Cl) of samples. A high-resolution laser  
410 incremental heating method of  $^{40}\text{Ar}/^{39}\text{Ar}$  dating allows us to resolve the admixture of phenocryst-hosted inherited  $^{40}\text{Ar}$  in the  
411 final temperature steps of the incremental step heating experiments. More than half of our  $^{40}\text{Ar}/^{39}\text{Ar}$  ages derived for this study  
412 are based on this method. All incremental step heating experiments are reproducible, except for the sample G15M0017 which  
413 gave the oldest age. The total fusion experiments of this study gave at least five times smaller analytical uncertainty (1SE on  
414 average  $\leq 0.01$  Ma) than the previous studies using conventional K-Ar (Angelier et al., 1977; Fytikas et al., 1976, 1986; Matsuda  
415 et al., 1999) and SHRIMP U/Pb zircon methods (Stewart and McPhie, 2006). Fission track dating on obsidians of the Milos  
416 VF produced two ages (Bigazzi and Radi, 1981; Arias et al., 2006) which seems to overlap with the K-Ar and  $^{40}\text{Ar}/^{39}\text{Ar}$  ages,  
417 but with larger uncertainty. U/Pb zircon ages could indicate the timing of zircon formation at high temperature ( $>1000$  °C) in  
418 magma chambers significantly prior to volcanic eruption (e.g. Flowers et al., 2005). On the other hand, the lower closure  
419 temperature of K-rich minerals ( $<700$  °C) makes the K-Ar and  $^{40}\text{Ar}/^{39}\text{Ar}$  ages better suited to determine the timing of extrusion  
420 of volcanic products (e.g. Grove and Harrison, 1996; Cassata and Renne, 2013).

421 The MSWD value, as a measure of the scatter of the individual step ages, is based on the error enveloping around the data  
422 point. The decrease in error will automatically cause an increase in MSWD (e.g. York, 1968; Wendt and Carl, 1991). The  
423 MSWD values reported in this study are relatively high. In part this is caused by the fact that modern multi-collector mass  
424 spectrometers used for  $^{40}\text{Ar}/^{39}\text{Ar}$  dating can measure the isotope ratios very precisely, which in turn would increase the MSWD.  
425 It will be more valuable and challenging to find a plateau or isochron age which meets the MSWD criteria ( $<2.5$ ) by modern  
426 multi-collector  $^{40}\text{Ar}/^{39}\text{Ar}$  dating than by K-Ar or  $^{40}\text{Ar}/^{39}\text{Ar}$  dating using a single detector instrument (e.g. Mark et al., 2009).  
427 Potential drawbacks of the  $^{40}\text{Ar}/^{39}\text{Ar}$  method are its dependence on neutron irradiation causing the production of interfering  
428 argon isotopes that need to be corrected for. The uncertainty in ages of standards that are required to quantify the neutron flux  
429 also need to be incorporated in the final ages as are uncertainties related to decay constants (supplementary material II). Finally,  
430 recoil can occur during irradiation. Minerals such as biotite can be prone to recoil, yielding slightly older ages (e.g. Hora et  
431 al., 2010).

432 Figure 13 compares previous published K-Ar, U/Pb zircon and fission track ages from the same volcanic units with the new  
433  $^{40}\text{Ar}/^{39}\text{Ar}$  data of this study. In general, there is a good agreement, however, six ages out of twenty-three differ significantly  
434 from previous studies that will be discussed below.

435 The obsidian fission track ages (Bigazzi and Radi, 1981; Arias et al., 2006) for the Dhemenehaki volcano are 0.25 My younger  
436 than the K-Ar ages (1.84 Ma, Angelier et al., 1977) and the  $^{40}\text{Ar}/^{39}\text{Ar}$  age of this study (1.825 Ma, G15M0032B). The good  
437 agreement between the K-Ar and  $^{40}\text{Ar}/^{39}\text{Ar}$  ages suggests that the fission track ages record another, lower temperature event,  
438 than the K-Ar and  $^{40}\text{Ar}/^{39}\text{Ar}$  ages. In addition, the larger uncertainty of fission track ages ( $>0.05$  Ma) also overlaps with the  
439  $^{40}\text{Ar}/^{39}\text{Ar}$  age at 2-sigma. We assume that the  $^{40}\text{Ar}/^{39}\text{Ar}$  age is the correct extrusion age for the obsidian of the Dhemenehaki  
440 volcano.

441 Angelier et al. (1977) reported one dacite sample in the northwest of Milos with an age of 1.71 Ma (Angelier\_3, location 3 on  
442 Figure 3 of Angelier et al., 1977). Argon loss could result in these ages (Angelier\_3-5 in Figure 13) being younger than our  
443  $^{40}\text{Ar}/^{39}\text{Ar}$  groundmass ages of  $1.97 \pm 0.01$  Ma (dacite sample G15M0021 and -22).

444 The amphibole of sample G15M0004 of the Adamas dacitic lava dome, located  $\sim 1$  km north of rhyolitic Bombarda volcano,  
445 gave an inverse isochron age of  $1.95 \text{ Ma} \pm 0.45 \text{ Ma}$ . This age overlaps with the K-Ar age for the Adamas lava dome of  $2.03 \pm$   
446  $0.06$  Ma (dacite M 66) of Fytikas et al. (1986). The large analytical uncertainty of our sample G15M0004 is caused by a

447 combination of low  $^{40}\text{Ar}^*$  yields and clustering of data points that define the inverse isochron showing excess argon was  
448 identified by the  $^{40}\text{Ar}/^{39}\text{Ar}$  method ( $^{40}\text{Ar}/^{36}\text{Ar}$  319.51  $\pm$  14.70), whereas the presence of excess argon cannot be tested by the  
449 K-Ar technique, implying that the Fytikas et al. (1986) might be slightly old.

450 The Korakia andesite has an age of 1.59  $\pm$  0.25 Ma (M 103, Fytikas et al., 1986) and was deposited in a submarine-subaerial  
451 environment on top of the Sarakiniko Formation that was dated based on paleomagnetic polarity in combination with a K-Ar  
452 age (1.80-1.85 Ma, Stewart and McPhie, 2003 and reference therein). The much older  $^{40}\text{Ar}/^{39}\text{Ar}$  groundmass age (2.68  $\pm$  0.01  
453 Ma) of Korakia andesite sample G15M0029 is unreliable and it could indicate the emplacement age of the Kalogeros  
454 cryptodome (2.70  $\pm$  0.04 Ma, Stewart and McPhie, 2006) or represents a geological meaningless age with only 23-27% of the  
455 total  $^{39}\text{Ar}$  released in the "plateau". In this case, the K-Ar age of 1.59  $\pm$  0.25 Ma is considered as the likely eruption age for the  
456 Korakia andesite although its argon loss or excess Ar component is unknown.

457 We obtained  $^{40}\text{Ar}/^{39}\text{Ar}$  ages of 3.41-4.10 Ma and 3.06  $\pm$  0.02 Ma, respectively, from the groundmasses of dacite samples  
458 G15M0017 and G15M0015 in the southwest of Milos (Figure 2 and 14B). Both of these samples are derived from the coherent  
459 dacite facies of the rhyolitic Profitis Illias volcano based on the Figure 11 of Stewart and McPhie (2006). Sample G15M0015  
460 yielded much higher radiogenic  $^{40}\text{Ar}$  (41.77%) than that of sample G15M0017 (<10% of  $^{40}\text{Ar}^*$ ), and the rhyolite sample M  
461 164 from Fytikas et al. (1986) (23.5% of  $^{40}\text{Ar}^*$ ) gave an estimate the eruptive age of 3.08  $\pm$  0.08 Ma to the Profitis Illias  
462 volcano which is much younger than that given by our sample G15M0017 (Figure 13). Therefore, we considered our  $^{40}\text{Ar}/^{39}\text{Ar}$   
463 ages of 3.06  $\pm$  0.02 Ma is the best estimate of the emplacement age of the coherent dacite facies of Profitis Illias volcano.

464 A basaltic andesite dyke near Kleftiko on the south-western coast of Milos has a K-Ar age of 3.50  $\pm$  0.14 Ma which only gave  
465 13.9% of  $^{40}\text{Ar}^*$  (Fytikas et al. 1986). This age is significantly older than the eruptive ages of Profitis Illias volcano which they  
466 intrude (Stewart, 2003). Although containing relatively low  $^{40}\text{Ar}^*$  (16.87%), our  $^{40}\text{Ar}/^{39}\text{Ar}$  age of 2.66  $\pm$  0.01 Ma with 67.27%  
467 of  $^{40}\text{Ar}^*$  from the groundmass of basaltic andesitic sample G15M0016 of the dyke near Kleftiko is probably an accurate  
468 intrusion age.

#### 469 **4.2 The published ages of other volcanic units**

470 Unfortunately, we were not able to date all key volcanic units of the Milos VF. This has three reasons (1) we did not collect  
471 samples from all units; (2) some of the collected samples were not fresh enough after inspection of thin sections; and (3) some  
472 of the  $^{40}\text{Ar}/^{39}\text{Ar}$  data indicates that the K-Ar decay system was disturbed. Therefore, we include published age information to  
473 establish a complete high-resolution geochronology for the Milos VF.

474 The published volcanic units that we include are the Profitis Illias volcano (3.08  $\pm$  0.08 Ma with 23.5 (%), Fytikas et al., 1986),  
475 the Mavro Vouni lava dome (2.50  $\pm$  0.09 Ma with 55.2  $^{40}\text{Ar}^*$  (%), Anglier et al., 1977) in the south-western part of Milos, the  
476 Bombarda volcano (1.71  $\pm$  0.05 Ma with 24.3  $^{40}\text{Ar}^*$  (%), Fytikas et al., 1986), the Plakes volcano (0.97  $\pm$  0.06 Ma with 10.2  
477  $^{40}\text{Ar}^*$  (%), Fytikas et al., 1986, and 0.8-1.2 Ma with 5.4-11.9  $^{40}\text{Ar}^*$  (%) Matsuda et al. 1999). Scoria deposits that Stewart and  
478 McPhie (2006) attributed to an andesitic scoria cone between Milos and Kimolos were produced insubmarine, and maybe  
479 occasionally above sea level. No age data for this deposit has been published so far. However, the stratigraphic position of  
480 this scoria deposit is between MIL 365 (2.66 Ma, Stewart and McPhie, 2006) and M103 (1.59 Ma, Fytikas et al., 1986), which  
481 is shown in Figure 10 of Stewart and McPhie (2006). Therefore, this scoria cone was likely active in the north-eastern part of  
482 the Milos VF between 2.6 and 1.6 Ma.

483 Fytikas et al. (1986) also analysed a pumice from the Sarakiniko deposits eastward of Adamas (1.85  $\pm$  0.10 Ma with 13.6  $^{40}\text{Ar}^*$   
484 (%), Fytikas et al., 1986) (Fig. 2). This unit is a reworked pyroclastic sediment of the Adamas lava dome (Rinaldi and Venuti,  
485 2003). Therefore, the K-Ar age from the Sarakiniko unit is not considered as an eruption age in this study. We did not sample  
486 the neighbouring islands of the Milos VF and also did not attempt to date the products of the recent phase of phreatic activity  
487 that Traineau and Dalabakis (1989) obtained  $^{14}\text{C}$  ages of 200 BC and 200 AD.

## 488 4.3 Implications for the stratigraphy of the Milos VF

### 489 4.3.1. Start of volcanism in the Milos VF.

490 Figures 13 and 14 summarize our stratigraphic interpretation of the Milos VF based on our new  $^{40}\text{Ar}/^{39}\text{Ar}$  ages in  
491 combination with previously published stratigraphic, biostratigraphic, fission track,  $^{14}\text{C}$ , K-Ar and U-Pb ages. We did not  
492 consider the Matsuda et al. (1999) data as the fission-track ages seem to be offset to other dating techniques ages obtained  
493 from the same deposits (see section 4.1 above). The exact start of volcanism in the Milos VF is still unclear since these older  
494 deposits are strongly hydrothermally altered. Van Hinsbergen et al. (2004) reported five ash layers in the Pliocene sedimentary  
495 rocks of southern Milos, ranging between 4.5-3.7 Ma in age, based on biostratigraphy, magnetostratigraphy and astronomical  
496 dating. In a slightly wider circle around Milos island, the  $6.943 \pm 0.005$  Ma a1-tephra event recorded in several locations on  
497 nearby Crete (Rivera et al., 2011), shows that explosive volcanism along the Aegean arc, possibly on Milos, already occurred  
498 during the Messinian. These ash beds cannot be traced to currently exposed centres in the Milos VF and could conceivably be  
499 related to volcanic centres further north (Antiparos and Patmos), which were active during this time interval (Vougioukalakis  
500 et al., 2019).

501 Biostratigraphy shows that the youngest layer with dateable fossils (bio-event, the last common occurrence of  
502 *Sphenolithus* spp., Van Hinsbergen et al., 2004) in the Neogene sedimentary rocks is 3.61 Ma old (GTS2020, Raffi et al.,  
503 2020). The diatomite Unit II from Calvo et al. (2012) on top of the oldest volcanoclastic deposit from the north-eastern coast  
504 of Milos is constrained within 2.83-3.19 Ma. These data suggest that the oldest products must be older than 2.83 Ma and  
505 younger than 3.61 Ma. Our oldest  $^{40}\text{Ar}/^{39}\text{Ar}$  ages of this study displayed a wide range of 3.41-4.10 Ma that are probably not  
506 correct due to alteration of the samples. Alteration might induce Ar loss and that would imply that the age is even older than  
507 3.4-4.1 Ma. The age of  $3.50 \pm 0.14$  Ma given by Fytikas et al. (1986) for an andesitic pillow lava or dyke has been discussed  
508 above and probably belongs to a series of basaltic andesite intrusions in the younger dacitic-rhyolitic deposits of Profitis Illias  
509 ( $\sim 3.08$  Ma, Fytikas et al., 1986), and therefore the 3.5 Ma age is probably not correct (e.g. Stewart, 2003). Fytikas et al. (1986)  
510 measured one sample from Kimolos (Figure 2 and 3) with an age of 3.34 Ma. Furthermore, Ferrara et al. (1980) reported an  
511 age of 3.15 Ma for a lithic clast derived from the Petalia intrusion in the Kastro volcanoclastics of Polyegos. If we assume that  
512 this reported age is a cooling age, volcanism in the Milos VF must have started before 3.15 Ma. Although age constraints for  
513 the start of volcanism on Milos both from the Neogene sedimentary rocks and the dated volcanic samples are poor, the evidence  
514 at this stage would suggest that volcanism in the Milos VF started  $\sim 3.3$  Ma ago.

### 515 516 4.3.2. Periods with different volumetric output.

517 The volume estimates of the Milos VF are hampered by limited exposure of several volcanic units and unknown age  
518 relationships. Therefore, not all units can be attributed to a certain volcano. Furthermore, we also do not know how much  
519 volcanic material was lost through transport by air, sea currents and erosion. Given the large errors on these estimates, we only  
520 considered the rough difference in density between extruded magma and the calculated DRE values. The volumetric  
521 contributions of the islands Polygos, Kimolos and Antimilos are not considered here. Therefore, the discussion here only  
522 provides a first order estimate of the onshore extruded magma volume. Taken into account all these limitations, our age data  
523 and the volume estimates by Stewart and McPhie (2006) likely indicate at least three periods of different long term volumetric  
524 volcanic output rates ( $Q_e$ ) throughout the Milos volcanic activity of  $\sim 3.3 - 0.0$  Ma. We define a "Period" as a time interval  
525 where the  $Q_e$  is significantly different from the average output rate of the Milos VF over the last 3.3 Ma. Figure 11 shows that  
526 the  $Q_e$  can be subdivided into two slow growth periods (I and III) and one period (II) during which the  $Q_e$  was significantly  
527 larger.

528 The lower boundary of Period I is based on our estimate of the first volcanic units of Milos at  $\sim 3.3$  Ma. These first  
529 units have been deposited in the SW of Milos between  $\sim 3.3$  and 3.08 Ma (see above) that were mapped as large pumiceous  
530 deposits of the basal pyroclastic series by Fytikas et al. (1986) and the felsic pumice cone/crypto dome facies by Stewart and

531 McPhie (2006). These deposits have a minimum thickness of 120m. The estimates of the DRE volume and  $Q_e$  of these earliest  
532 volcanic deposits are hampered by the lack of precise age information, the high degree of alteration and structural complexities.  
533 Therefore, we only calculated the  $Q_e$  of Period I since 3.08 Ma from which the eruption products are mainly dacitic-rhyolitic  
534 in composition (Table 5, Fig 11), and the first products that can be reliably dated are cryptodomes (3.06 Ma, sample G15M0015)  
535 and dikes (2.66 Ma, sample G15M0016) into the older basal pyroclastic series of Fytikas et al. (1986) or the units of Profitis  
536 Illias volcano of Stewart and McPhie (2006, 3.08 Ma) in the SW of Milos. This was followed by the formation of the submarine  
537 Fylakopi pumice cone volcano at 2.66 Ma (Stewart and McPhie, 2006) and Kalogeros cryptodome at 2.62 Ma (sample  
538 G15M0006) in the north-eastern part of Milos. These two pumice cone volcanoes contributed 3-11 km<sup>3</sup> DRE in volume to the  
539 Milos VF. The last two volcanic activities of Period I occurred in the SW (Mavro Vauni, 2.50 Ma, Angelier et al., 1977) and  
540 west of Milos (Mavros Kavos, 2.36 Ma, this study), respectively, which produced two high-aspect-ratio andesitic-dacitic lava  
541 domes with a total volume of 1-3 km<sup>3</sup> DRE (Stewart and McPhie, 2006). During Period I, which lasted ~ 1 Myr, the estimated  
542  $Q_e$  is  $0.9 \pm 0.5 \times 10^{-5}$  km<sup>3</sup>.yr<sup>-1</sup>.

543 The change from Period I to II is based on the sharp increase in  $Q_e$  of Figure 11 at 2.13 Ma. During this period the  $Q_e$   
544 ( $3.0 \pm 1.7 \times 10^{-5}$  km<sup>3</sup>.yr<sup>-1</sup>) increased by a factor of ~3 compared to the Period I and III. Period II starts with the extrusions of  
545 the dacitic-rhyolitic Triades lava dome in the north-west and dacitic Adamas lava dome in the north-east of Milos and is  
546 followed by the rhyolitic Dhemenehaki pumice cone/cryptodome and the Bombardo volcano in the north-east of Milos. For  
547 the Bombarda centre a large age range is reported in the literature (1.71-2.15 Ma, Fig. 13B). We were not successful to date  
548 samples from the Bombarda centre, but Rinaldi and Campos Venuti (2003) reported that an age of 1.71 Ma is the best  
549 approximation based on other stratigraphic information. For the Dhemenehaki centre, we obtained a <sup>40</sup>Ar/<sup>39</sup>Ar age of 1.825  
550 ± 0.002 Ma from obsidian. The Triades, Adamas, Dhemenehaki and Bombarda centres all developed in a submarine setting,  
551 as the intercalated sediments from the northern coast of Milos show (Calvo et al., 2012; see Fig. 14). The last two volcanic  
552 expressions in Period II consists of two submarine-to-subaerial lava dome extrusions, Kantaro (1.59 Ma, Fytikas et al., 1987)  
553 and Korakia (1.48 Ma, this study) in the north-west and north-east of Milos, respectively. The products of these two centres  
554 are andesitic-dacitic in composition. All volcanic centres of Period II produced 8-30 km<sup>3</sup> DRE in volume for the Milos VF.  
555 Each dome of Period II has a massive core and flow banded rind surrounded by an in-situ autobreccia zone (Stewart and  
556 McPhie, 2006).

557 Period III starts with a time interval of 0.4 Ma with no eruptions and has a very low  $Q_e$  of  $0.25 \pm 0.05 \times 10^{-5}$  km<sup>3</sup>.yr<sup>-1</sup>.  
558 The boundary between Period II and III can be placed at the last eruption of Period II, at the start of the first eruption in the  
559 low output interval, or halfway in between. The difference between those options is not significant, given the large uncertainties  
560 of the volume estimates (Fig. 12), and therefore we have decided to start Period III directly after the last eruption of the high  
561  $Q_e$  of Period II. The composition of nearly all Period III volcanic products is rhyolitic, an exception is the dacitic Plakes lava  
562 dome (Fig. 12). The Plakes lava dome is probably the last volcano erupting at ~0.97 Ma (Fytikas et al., 1987) in a submarine  
563 environment in the north of Milos, whereas the other lava dome in Period III, Halepa, produced rhyolitic lavas in a subaerial  
564 setting in the south (Stewart and McPhie, 2006). The Halepa and Plakes domes contributed 1-3 km<sup>3</sup> DRE in volume to the  
565 Milos VF and were followed by a 0.3 Ma interval with no or limited volcanic eruptions. Two subaerial pumice cone volcanoes  
566 with biotite bearing rhyolites were constructed during the last 0.6 Ma: Trachilias and Fyriplaka complexes. The Trachilias  
567 complex was active for approximately 300 kyr (0.63-0.32 Ma) in the northern part of Milos. The evolution of this complex  
568 starts with phreatic eruptions which became less explosive over time (Fytikas et al., 1986). During the last eruption ( $0.317 \pm$   
569  $0.004$  Ma) of the Trachilias complex rhyolitic pumices filled up the crater area and did breach the northern tuff cone walls.  
570 The Trachilias complex only added a small volume (1-2 km<sup>3</sup> DRE) of material to the Milos VF. The Kalamos lava dome was  
571 also extruded in the south of Milos (Fig. 2) contemporaneously with the Trachilias complex.

572 The youngest volcanic activity of Milos (0.11 Ma-present), is characterized by subaerial eruptions of biotite phyric  
573 rhyolite from the Fyriplaka complex in the south of Milos, and was studied in detail by Campos Venuti and Rossi (1996). This

574 complex is constructed on a paleosol that developed in a phreatic deposit (“Green Lahar”, Fytikas et al., 1986) or lies directly  
575 on the metamorphic basement. Campos Venuti and Rossi (1996) indicated that the stratigraphic order is: Fyriplaka and Gheraki  
576 tuff rings, Fyriplaka lava flow, composed tuff cone of Tsigrado-Provatas. The tuff ring of Fyriplaka was divided into three  
577 members, with on top the deposits of the Tsigrado tuff cone. The total estimated volume of volcanic material is 0.18 km<sup>3</sup> DRE.  
578 The boundary between the Fyriplaka and Tsigrado tuff cones is characterized by a marked erosive unconformity. The  
579 composition of these young volcanic products is very constant (Fig. 10-11), this was also noted by Fytikas et al (1986) and  
580 Campos Venuti and Rossi (1996). The products from Fyriplaka and Tsigrado cones are covered with a paleosol rich in  
581 archaeological remains and a phreatic deposit consisting largely of greenschist metamorphic fragments. According to Campos  
582 Venuti and Rossi (1996), the Fyriplaka cone was quickly built by phreatic and phreatomagmatic eruptions, as there are no  
583 paleosols observed between the different units. However, our data do suggest a large range in ages between 0.11 and 0.06 Ma.  
584 Fytikas et al. (1986) also reported a range between 0.14 and 0.09 Ma. These ages are inconsistent with the “Green Lahar” age  
585 of 27 kyrs (Principe et al., 2002), suggesting that the “Green Lahar” deposit consists of many different phreatic eruption layers  
586 that were formed during a time interval of more than 0.4 Ma, as the Kalamos lava is underlain by a green phreatic eruption  
587 breccia (Campos Venuti and Rossi 1996). We, therefore, conclude that phreatic eruptions occurred for more than 400 kyr,  
588 predominately in the eastern part of Milos until historical times (200 BC – 200 AD, Traineau and Dalabakis, 1989).

#### 589 4.3.3. *Temporal evolution of the magma plumbing system of the Milos VF.*

591 Figure 11 shows several of the temporal petrographic and major-element variations during the evolution of the Milos VF. The  
592 chemistry of the magmas did not change significantly between the three different periods, for example, the K<sub>2</sub>O/SiO<sub>2</sub> ratio is  
593 constant (0.05 ±0.02) with one exception, sample G15M0021 collected near Cape Vani which is altered by hydrothermal  
594 processes (e.g. Alfieris et al. 2013). The volcanic units of Period III are dominantly rhyolitic in composition, whereas during  
595 Period I and II the compositions of volcanic units range between basaltic-andesite to rhyolite. The crystallinity of the volcanic  
596 products is low (<10 vol.%) during Period III because most of these products are pumiceous. Although there is also a large  
597 number of pumiceous units of low crystallinity produced by Profitis Illias and Fylakopi volcanoes during Period I (Stewart  
598 and McPhie, 2006), the crystallinity of the other products of Period I and most of Period II units are much higher (20-40 vol.%)  
599 than that of Period III. In addition, we observed that the volcanic products of Period II have the lowest vesicularity (<10 vol.%),  
600 compared to the highly variable vesicularity of Period I (1-50 vol.%) and the high value for Period III (10-100 vol.%). These  
601 observations are consistent with the type of volcanic structures. Period I and III contain large explosive pumice cone volcanoes,  
602 whereas Period II is dominated by effusive dome extrusions. The extrusion of crystal-rich, outgassed and thus viscous residual  
603 magmas in large volumes during Period II is similar to the description for the effusive volcanism of the Methana VF (Popa et  
604 al., 2020). Popa et al. (2020) suggested that the critical factor controlling the effusive-explosive transitions of Methana is the  
605 crystallinity of the erupted material based on their petrological data. The crystallinity has a higher influence on the bulk  
606 viscosity of magma than the other factors (e.g. water content and composition; Popa et al., 2020). A higher crystallinity results  
607 in a slower ascent velocity of magma and enhances the formation of permeable pathways in the conduit for the gas, which  
608 promotes the outgassing of the magmas and leads to effusive behaviour. Lower crystallinity (<30 vol.%) of the magmas results  
609 in explosive eruptions and has the opposite effect on outgassing, which causes high vesicularity of the eruption products.  
610 Popa et al. (2020) showed that different magma plumbing systems are responsible for the explosive (crystal-poor) and effusive  
611 (crystal-rich) eruptions of Methana (Popa et al., 2020, their Fig. 13). For the effusive lava domes of Period II, the composition  
612 mainly ranges from basaltic-andesitic to dacitic, and the petrological observations of the dacite sample G15M0019 and -20 of  
613 the Kantaro dome show the presence of olivine-clinopyroxene-orthopyroxene cumulates and amphibole-biotite reaction rims  
614 (supplementary material I). The andesite of the Korakia dome (G15M0029) has a groundmass of acicular plagioclase and  
615 plagioclase phenocrysts with sieve textures. These petrological observations suggest large scale magma mixing between felsic  
616 and more mafic magma, consistent with the hybridized magmas of the effusive events on Methana (e.g. Popa et al., 2020). The

617 pumiceous units of the explosive volcanoes on Milos during Period I and III could be caused by mafic magmas that intrudes a  
618 magma reservoir filled with felsic magma. This is consistent with the suggestion of Fytikas et al. (1986) that the main location  
619 of feeding magma for the Milos VF is in the lower part of the crust from Pliocene to Pleistocene ( $\approx$ Period I).  
620 It is noteworthy that the value of the  $Q_e$  ( $0.2-4.7 \times 10^{-5} \text{ km}^3 \cdot \text{yr}^{-1}$ ) for the Milos VF is at least 2-3 orders lower than the average  
621 for rhyolitic systems ( $4.0 \times 10^{-3} \text{ km}^3 \cdot \text{yr}^{-1}$ ) and the mean for continental arcs ( $\sim 70 \times 10^{-3} \text{ km}^3 \cdot \text{yr}^{-1}$ ) with a range of  $8 \times 10^{-6} -$   
622  $9 \times 10^{-2} \text{ km}^3 \cdot \text{yr}^{-1}$  (White et al., 2006). Milos overlaps with the lowest  $Q_e$  values of the study of White et al. (2006). For the  
623 magma supply rate underneath the Milos VF, although no data are available for the ratio between intruded magma in the crust  
624 below Milos and extruded volcanics (I:E), White et al. (2006) argue that a ratio of 5:1 is probably a realistic estimate for most  
625 volcanic centres and that this ratio can be higher in volcanic centres constructed on continental crust. This would result in a  
626 magma supply rate from the mantle beneath the Milos VF in the order of  $0.1-3.3 \times 10^{-4} \text{ km}^3 \cdot \text{yr}^{-1}$ . Compared with other SAVA  
627 volcanic centres, Druitt et al. (2019) reported a long-term average magma supply rate of approximately  $1 \times 10^{-3} \text{ km}^3 \cdot \text{yr}^{-1}$   
628 beneath the Kameni islands of Santorini, which is comparable to that of the Milos. Besides the case of Santorini VF, no other  
629 information on the long-term average magma supply rate of other volcanic centres of the SAVA is available to our knowledge.  
630 Given that the island of Milos is approximately 15 km long (W-E), this results in a magma production rate over the last  $\sim 3.34$   
631 Ma of approximately  $0.7-22 \text{ km}^3 \cdot \text{km}^{-1} \cdot \text{Myr}^{-1}$ . Although this magma production rate per km arc length is the onshore estimate  
632 for the Milos VF, it is still significant lower than for oceanic arcs:  $157-220 \text{ km}^3 \cdot \text{Myr}^{-1} \cdot \text{km}^{-1}$  (Jicha and Jagoutz, 2015). For  
633 continental arcs the long-term magma production rate is more difficult to establish because magmatism is cyclic, and short  
634 periods (5-20 Ma) of intense magmatism (“flare ups”) with  $85 \text{ km}^3 \cdot \text{km}^{-1} \cdot \text{Myr}^{-1}$  are alternating with periods of 25-50 Ma of low  
635 magma production rate of  $20 \text{ km}^3 \cdot \text{km}^{-1} \cdot \text{Myr}^{-1}$  (e.g. Jicha and Jagoutz, 2015). The periods of low magma production overlap  
636 with the magma production rates beneath the Milos VF over the past  $\sim 3.34$  Ma.

## 637 5 Conclusion

638 This study reports twenty-one new  $^{40}\text{Ar}/^{39}\text{Ar}$  ages and major element data for 10 volcanic units of the Milos Volcanic Field.  
639 In combination with previously published age data, geochemistry and facies analysis the following points can be made.

- 640 (1) The exact age of the start of volcanism in the Milos VF is still unclear due to the high degree of alteration of the oldest  
641 deposits. The best estimate is based on our new  $^{40}\text{Ar}/^{39}\text{Ar}$  ages, published K-Ar data and nannofossil biozones is  
642 between 3.5 and 3.15 Ma.
- 643 (2) Based on the long-term volumetric volcanic output rate, the volcanic history of the Milos VF can be divided into two  
644 slow growth periods, Period I ( $\sim 3.3-2.36$  Ma) and III (1.48 Ma-present), and one relatively fast growth period, Period  
645 II (2.36-1.48 Ma).
- 646 (3) Period I and III are dominated by low crystallinity, highly vesicular pumice deposits, whereas Period II is  
647 characterised by dominantly dome extrusions with low vesicular, high crystallinity products.
- 648 (4) Large scale magma mixing between felsic and more mafic magma in the upper crust underneath Milos probably result  
649 in the high crystallinity of the effusively eruptive units of Period II. During Period I and III, the pumiceous units of  
650 the explosive volcanoes on Milos could be caused by mafic magma from deep that intrudes a magma reservoir filled  
651 with felsic magma. The evolution of the Milos VF volcanic rocks changed over time in composition from basaltic-  
652 andesite-rhyolite volcanism to mainly rhyolite. The long term volumetric volcanic output rate of Milos is  $0.2-4.7 \times 10^{-5}$   
653  $\text{ km}^3 \cdot \text{yr}^{-1}$ , 2-3 orders of magnitude lower than the average for rhyolitic systems and continental arcs.

654

655 **Acknowledgement**

656 We would like to thank Roel van Elsas with the assistance of rock crushing and mineral separation. Kiki Dings helped with  
657 the XRF bead preparation and measurements. Lara Borst and Onno Postma assisted with the  $^{40}\text{Ar}/^{39}\text{Ar}$  dating. We acknowledge  
658 the Greek Institute of Geology and Mineral Exploration (IGME) for permission to conduct fieldwork on Milos. Xiaolong Zhou  
659 would like to acknowledge a grant no. 201506400055 from the China Scholarship Council (CSC). The  $^{40}\text{Ar}/^{39}\text{Ar}$  facility of the  
660 VU is covered by NWO grant 834.09.004. This research benefitted from funding from the European Research Council under  
661 the European Union's Seventh Framework Programme (FP7/2007-2013)/ERC grant agreement n° 319209. A previous version  
662 of this manuscript greatly benefitted from a very detailed and constructive review by Dr. J. McPhie. A second review by Dr J.  
663 McPhie and Dr. J-F. Wotzlaw helped to clarify the interpretation of the geochronology of Milos. We thank Drs. J. Nadden, J.  
664 Miles and S Tapster for pointing out mistakes in our figures.

The age in bold is considered as the best estimate of the eruptive age.

The  $^{40}\text{Ar}^*$  (%) is the average radiogenic  $^{40}\text{Ar}$  of the analyses included in the weighted mean.

The experiment was analyzed on biotite<sup>B</sup>, obsidian<sup>O</sup>, amphibole<sup>A</sup> and groundmass<sup>G</sup> of a sample.

The same steps were used for the calculation of isochron ages as used in the weighted mean ages.

The age in bold is considered as the best estimate of the eruptive age.

The  $^{40}\text{Ar}^*$  (%) is the average radiogenic  $^{40}\text{Ar}$  of the analyses included in the weighted mean.

\*The K/Ca ratio is calibrated by removing the total fusion with excess  $^{37}\text{Ar}$  (Ca) (fA>1).

<sup>B</sup>The experiment was analyzed on biotite of the sample.

The same steps were used for the calculation of isochron ages as used in the weighted mean ages.

**Table 5. Summary of the eruption ages of the Milos volcanic field**

No.	Name of volcanic centre	Age (Ma)	Reference
1	Kimlos volcano	3.34	Fytikas et al., 1986
2	Profitis Illias crypto/pumice cone	3.08	Fytikas et al., 1986
3	coherent dacite of Profitis Illias volcano	3.06	This study
4	Filakopi volcano	2.66	Stewart and McPhie, 2006
5	Kalegeros cryptodome	2.62	This study
6	Mavro Vouni lava dome	2.5	Angelier et al., 1977
7	Mavros Kavos lava dome	2.42-2.36	This study
8	Polyegos lava dome	2.34	Fytikas et al., 1986
9	Triades lava dome	2.13-2.10 and 1.97	This study
10	Adamas lava dome	2.03	Fytikas et al., 1986
11	Dhemeneghaki volcano	1.83	This study
12	Bombardo volcano	1.71	Fytikas et al., 1986
13	Korakia dome	1.59	Fytikas et al., 1986
14	Komntaro dome	1.52-1.48	This study
15	Halepa lava dome	1.04	This study
16	Plakes lava dome	0.97	Fytikas et al., 1986
17	Trachilias complex	0.63, 0.51 and 0.317	This study
18	Kalamos lava dome	0.41	This study
19	Antimilos domes	0.32	Fytikas et al., 1986
20	Fyriplaka complex	0.11 and 0.07-0.06	This study
21	Phreatic activity	200 AD-200 BC	Trainau and Dalabakis, 1989

Figure 1. Map of the South Aegean Volcanic Arc (SAVA). Volcanic fields (VF) are indicated by red triangles: Susaki, Methana and Milos VFs in the western SAVA, Santorini VF in the centre and Nisyros VF in the eastern SAVA. Red contour lines show the depth to the Benioff zone (Hayes et al., 2018). White arrow represents the GPS-determined plate velocity of the Aegean microplate relative to the African plate from Doglioni et al. (2002).

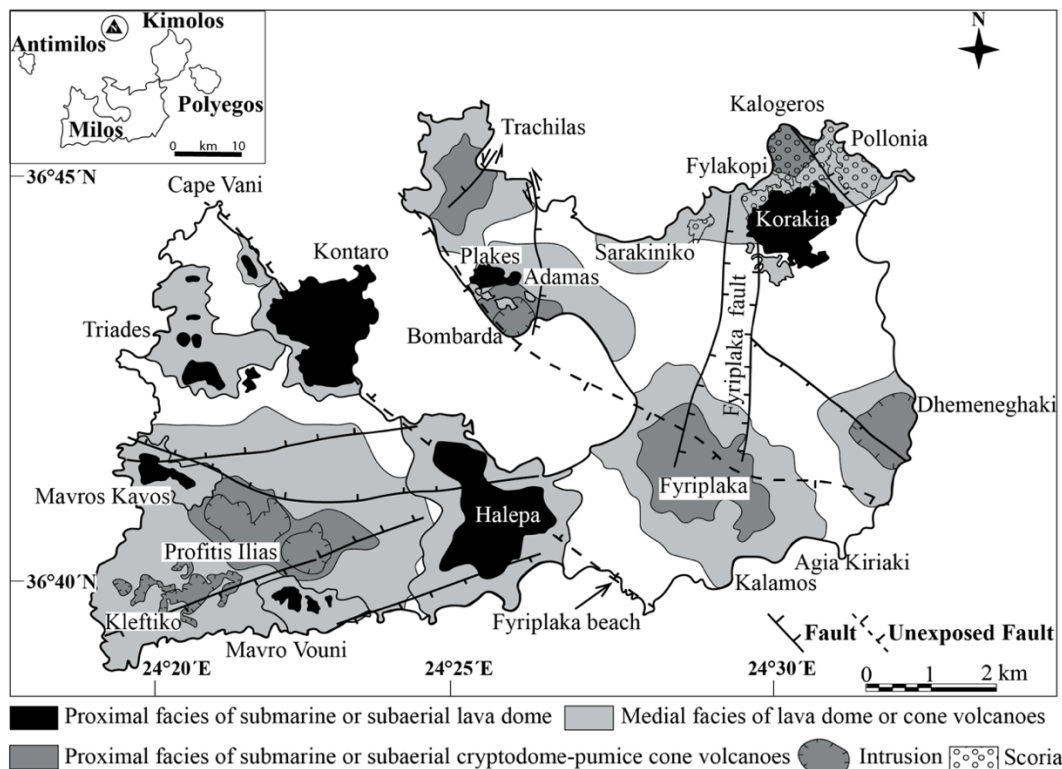

Figure 2. Distribution of the proximal and medial facies of the submarine pumice cone/cryptodome volcanoes, submarine, submarine-subaerial and subaerial domes and rhyolitic complexes (tuff cone and associated lava) of Milos, modified after Fytikas et al. (1986) and Stewart and McPhie (2006). The distal facies of Stewart and McPhie (2006) is not shown.

Figure 3. Simplified geological map of Milos with our  $^{40}\text{Ar}/^{39}\text{Ar}$  ages and sample locations of key volcanic deposits, modified after Stewart and McPhie (2006) and Grasemann et al. (2018). The stratigraphic units of Milos are from Fytikas et al. (1986). Age data from this study are in black, published ages are shown in red (Angelier et al., 1977, Fytikas et al., 1986, Traineau and Dalabakis, 1989, and Stewart and McPhie, 2006). The "Green Lahar" (Fytikas, 1977) consists of deposits from multiple phreatic explosions and contains fragments of metamorphic, sedimentary and volcanic rocks.

Figure 4. Previous proposed stratigraphic frameworks for Milos by Angelier et al. (1977), Fytikas et al. (1986) and Stewart and McPhie (2006). Volcanic unit II of Angelier et al. (1977) contains unit I. Stewart and McPhie (2006) described the volcanic faces of Milos mainly based on the geochronological works of Angelier et al. (1977) and Fytikas et al. (1986). Abbreviation: SFCPCV=Submarine felsic cryptodome-pumice cone volcanoes.

(A) G15M0016-Basaltic-andesitic dyke of the Mavro Vouni dome (B) G15M0032B-Obsidian of the Dhemenehaki volcano

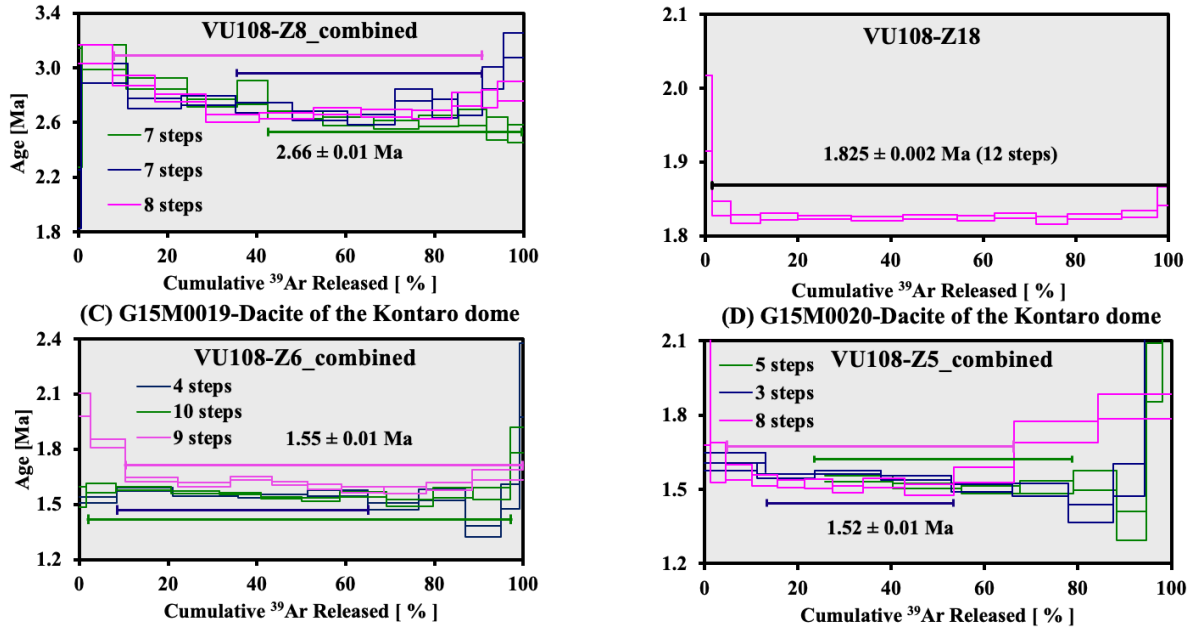

Figure 5. Groundmass  $^{40}\text{Ar}/^{39}\text{Ar}$  plateau ages for samples G15M0016 (A), G15M0032B (B), G15M0019 (C) and G15M0020 (D). The Mavro Vouni dome (A), Dhemenehaki volcano (B) and Kontaro dacitic dome (C, D) are located in respectively the south-western, north-eastern and eastern parts of Milos VF (see Fig. 2). Final age calculation is reported with  $1\sigma$  errors. See the individual steps of sample G15M0016, G15M0019 and G15M0029 in supplementary material II.

Figure 6. Groundmass  $^{40}\text{Ar}/^{39}\text{Ar}$  plateau or inverse isochron ages for samples G15M0017 (A), G15M0015 (B) and G15M0029 (C). Individual steps and final age calculation are reported with  $1\sigma$  errors. The Profitis Illias volcano (A, B) and dacitic Korakia dome (C) are located in the south-western and north-eastern parts of Milos VF, respectively (see Fig. 2). See the individual steps of sample G15M0015 and G15M0029 in supplementary material II.

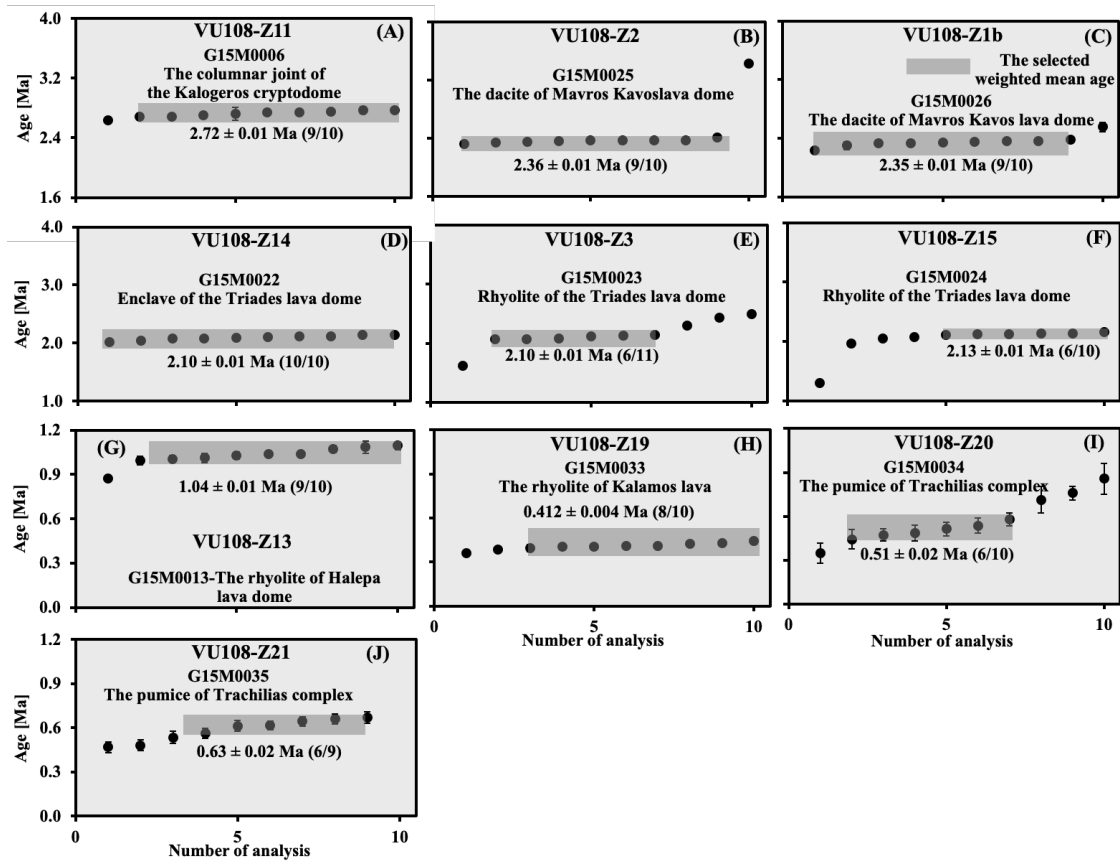

Figure 7. Biotite  $^{40}\text{Ar}/^{39}\text{Ar}$  total fusion ages for samples G15M0006 (A) and G15M0025-26(B, C), G15M0022-24 (D-F), G15M0013 (G) and G15M0033-35 (H-J). Data outside shaded area are not included in the weighted mean. Individual steps and final age calculation are reported with  $1\sigma$  errors. The Kalogeros cryptodome and Mavros Kavos lava dome are located in the north-eastern and south-western parts of Milos VF, respectively, and Triades lava dome, Halepa lava dome, Trachilias complex and the Kalamos lava are situated in the southern, northern and south-eastern parts of Milos VF, respectively (see Fig. 2).

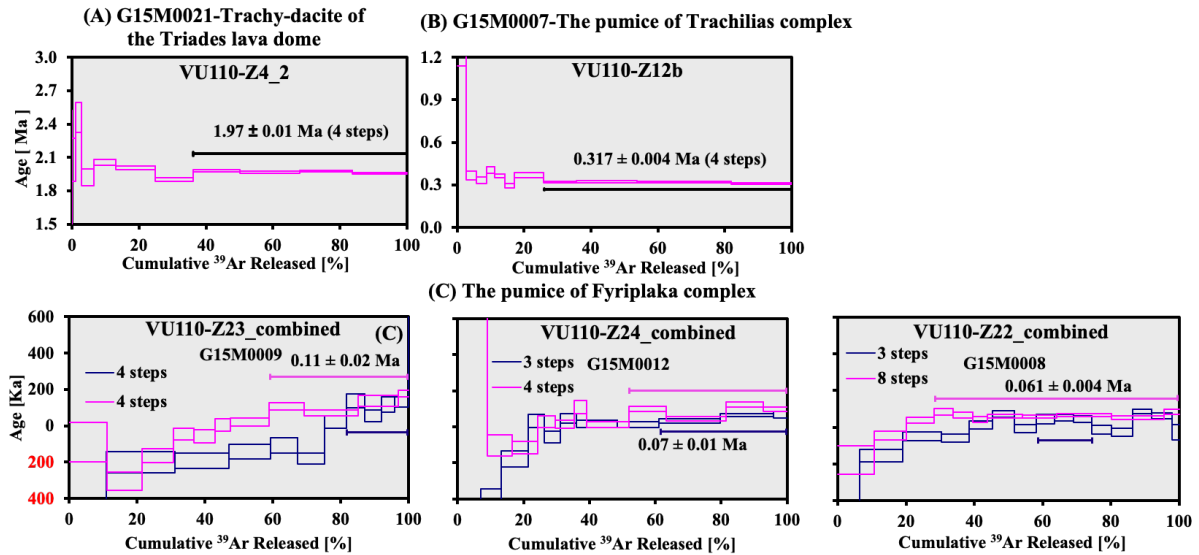

Figure 8. Biotite  $^{40}\text{Ar}/^{39}\text{Ar}$  plateau ages for samples G15M0021 (A), G15M0007 (B), and G15M0009 (VU110-Z23\_combined), G15M0012 (VU110-Z24\_combined) and G15M0008 (VU110-Z22\_combined) (C). The numbers in red represent negative ages. Individual steps and final age calculation are reported with  $1\sigma$  errors. The Triades lava dome, Trachilias and Fyriplaka complexes are located in the north-western, northern and south-eastern parts of Milos VF, respectively (see Fig. 2). See the individual steps of sample G15M0021, G15M0007, G15M0009, G15M0012 and G15M0008 in supplementary material II.

Figure 9. Amphibole  $^{40}\text{Ar}/^{39}\text{Ar}$  plateau or inverse isochron ages for samples G15M0004 (A) and G15M0026 (B). Final age calculation is reported with  $1\sigma$  errors. The Adamas and Mavros Kavos lava domes are located in the northern and south-western parts of Milos VF, respectively (see Fig. 2). See the individual steps of sample G15M0004 and G15M0026 in in supplementary material II.

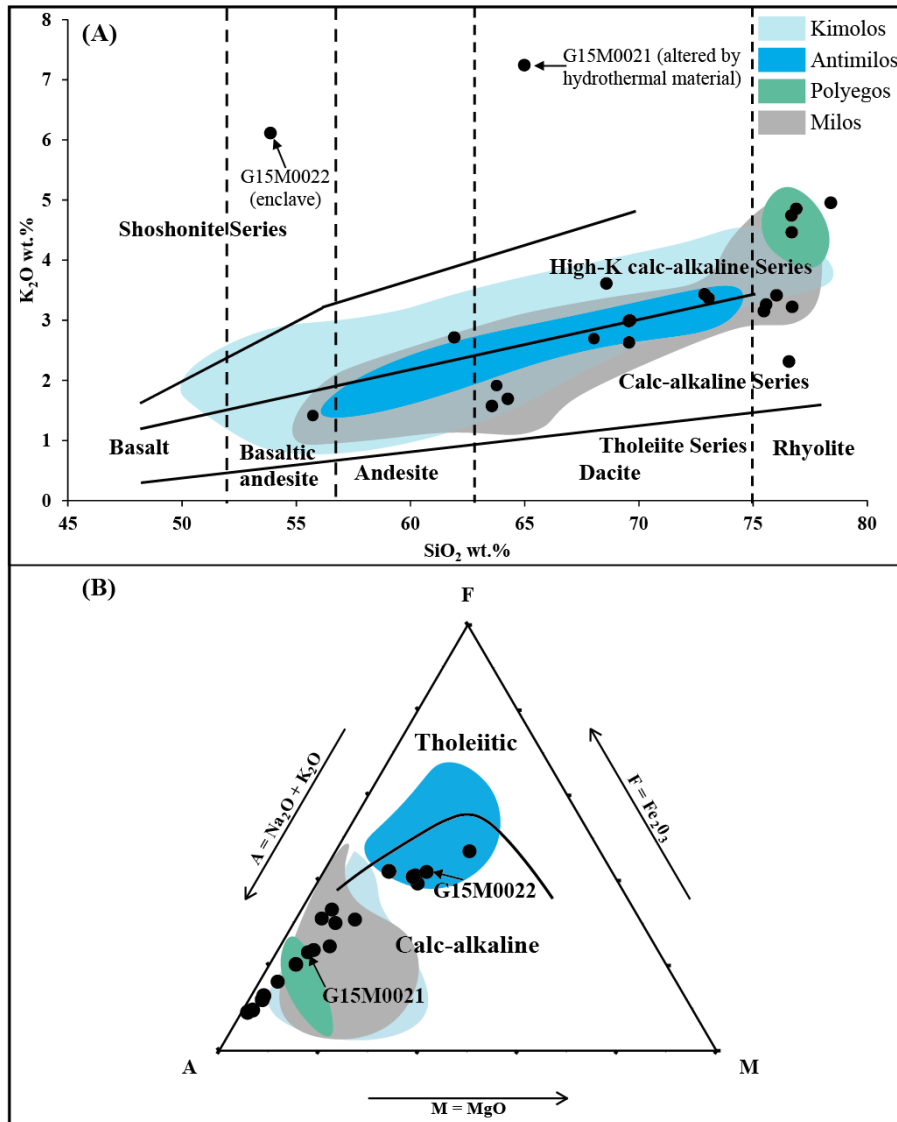

Figure 10.  $\text{SiO}_2$  versus  $\text{K}_2\text{O}$  (A) and AFM (B) diagrams for the Milos volcanic field with data of this study as solid circles. Published data are represented by shaded fields (Francalanci and Zelmer, 2019 and reference therein). Fields for the tholeiite, calc-alkaline, high-K calc-alkaline and shoshonitic series are from Peccerillo and Taylor (1976). Vertical lines defining fields for basalt, basaltic-andesite, andesite, dacite and rhyolite are from Le Bas et al. (1986). The solid line dividing tholeiitic and calc-alkaline fields is from Irvine and Baragar (1971).

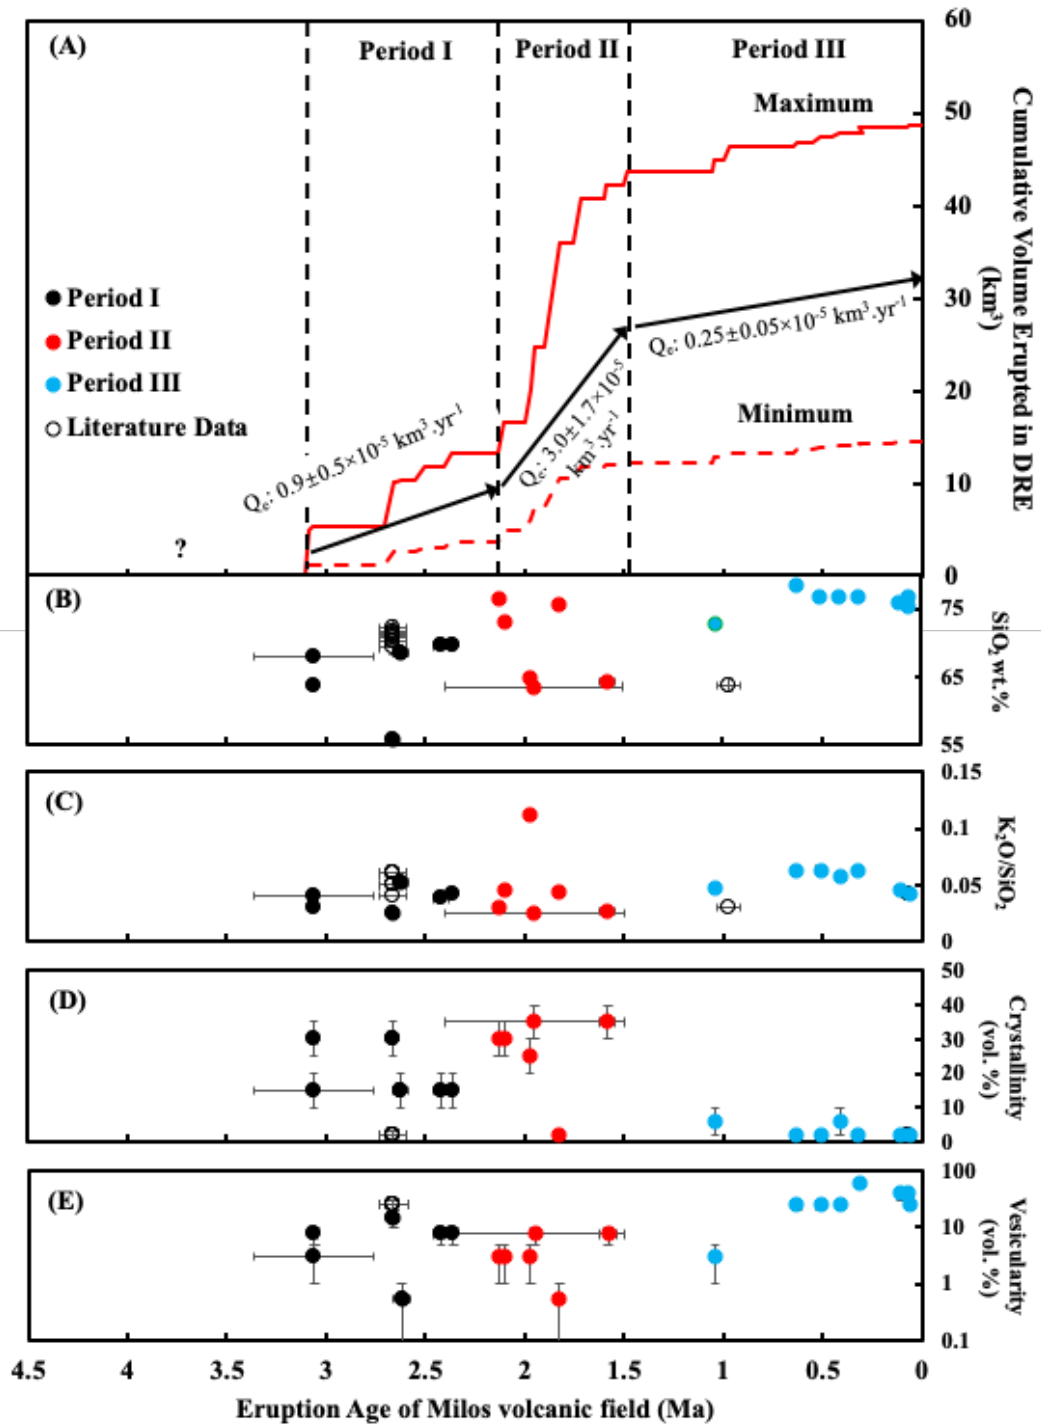

Figure 11. Eruption age versus (A) cumulative eruption volume for the volcanic deposits of Milos, (B) SiO<sub>2</sub> wt.%, (C) K<sub>2</sub>O/SiO<sub>2</sub>, (D) crystallinity vol. % and (E) vesicularity vol. % of Milos volcanic units of this study and previous studies. The maximum (Max; red line) and minimum (Min; dashed red line) cumulative eruption volume curves were estimated from Campos et al. (1996) and Stewart and McPhie (2006). Q<sub>e</sub> is the long term volumetric volcanic output rate (see discussion). The exact volume of volcanic products between 4.1 and 3.08 Ma is not well constrained and indicated with a question mark. In this study, the estimations of crystallinity and vesicularity on the older samples (>1.0 Ma) are all from lava and domes. Most of the younger samples (<1.0 Ma) are pumiceous pyroclastic units. The major element, crystallinity and vesicularity data of the old pumices of Filakopi volcanoes (2.66 Ma) are from Stewart (2003). The major element data of the Plakes lava dome is from Fytikas et al. (1986). Geochemical, crystallinity and vesicularity data of the old pumices of the Profitis Illias (~3.08 Ma) is lacking due to the severe alteration.

Figure 12. The  $^{40}\text{Ar}/^{39}\text{Ar}$  ages of this study (x-axis) compared to the K/Ar ages (Angelier et al., 1977; Fytikas et al., 1986), U/Pb zircon ages (Stewart and McPhie, 2006) and fission track ages (Bigazzi and Radi, 1981; Arias et al., 2006) (y-axis) for the same volcanic units. Ages which deviate from the 1:1 correlation line are discussed in section 4.1.

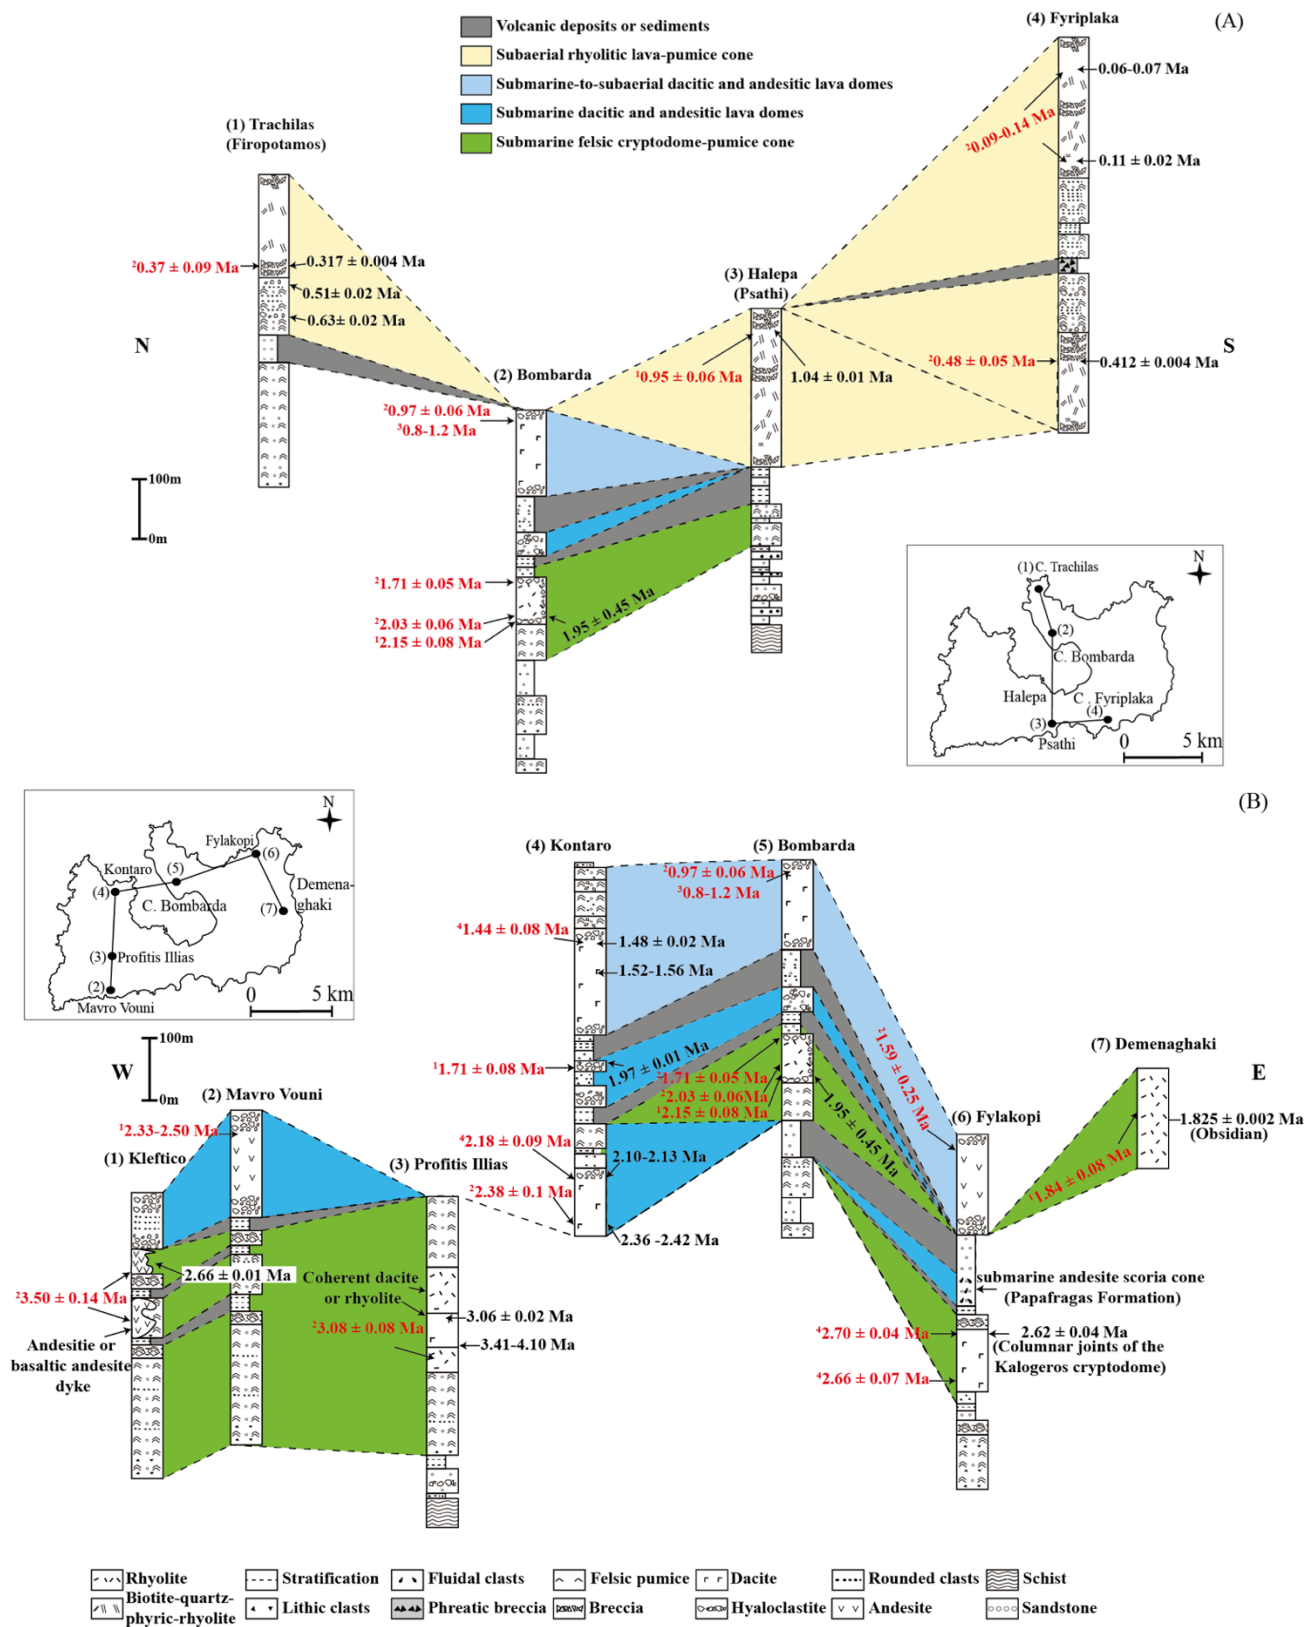

Figure 14. Nine selected stratigraphic columns covering the (A) young (<1.4 Ma) and (B) old (>1.4 Ma) volcanic deposits of Milos modified after Stewart and McPhie (2006), except for (7) Demenaghaki. Age data in black are from this study and in red are from: 1=Angelier et al. (1977), 2=Fytikas et al. (1976, 1986), 3=Matsuda et al. (1999), 4=Stewart and McPhie (2006).

Figure 14. Diagram presenting three periods of different long term volumetric volcanic output rate on Milos volcanic field based on the new  $^{40}\text{Ar}/^{39}\text{Ar}$  data of this study and published data. The location of the different volcanoes is given in Fig 2 and indicated in the left panel (from left to right: SW, W, NW, N, NE, E, SE and S of Milos). The right panel corresponds to published age data: [A]=Fytikas et al., 1976, [B]=Angelier et al., 1977, [C]=Fytikas et al., 1986, [D]= Bigazzi & Radi, 1981, [E]=Matsuda, 1999, [F]=Stewart and McPhie (2006), [G]= Trainau and Dalabakis, 1989, and Biostratigraphic data of the Neogene sediments (NG) is from [H]=Calvo et al. (2012) and [I]=Van Hinsbergen et al. (2004) calibrated to Raffi et al. (2020) (LCO of *Sphenolithus* spp. and FO of *D. tamalis*). The number in the left panel represents the volcanic centres of Milos (see details in Table 5). The start of volcanism (3.08-3.61 Ma) on Milos and the basement of the other Islands (Antimilos, Kimolos and Polyegos) are not well constraint and indicated with question marks (see text for discussion). The simplified basement cross-section (NS: Neogene sedimentary rock; MB: Metamorphic basement) under Milos volcanic units is based on Fytikas et al. (1989). We used the filled symbols as the best estimate for the eruption ages at the different volcanic centres.
