

Interactive comment on “TephraNZ: a major and trace element reference dataset for prominent Quaternary rhyolitic tephras in New Zealand and implications for correlation” by Jenni L. Hopkins et al.

Stephen Kuehn (Referee)

sckuehn@concord.edu

Received and published: 8 January 2021

The core purpose of this paper is to present and evaluate a set of New Zealand tephra reference data to provide an openly-available framework and database to support tephra-using multidisciplinary research. To facilitate unambiguous eruption identification, samples from key reference locations have been characterized using a consistent, well-described methodology. This dataset is then examined to outline where tephra identifications may still be challenging, even with such consistent data.

Discussion paper

The paper follows many recommended best practices in tephra data reporting (e.g. including detailed methods, reporting H2OD, reporting results on quality control standards), but it could go further. With additional documentation, better data filtering, and better exploration of deposit heterogeneity it could become outstanding example.

The authors also discuss the importance of data repositories, yet this dataset appears to exist only as Excel tables currently. Are there specific plans to house the TephraNZ dataset in an open database system that supports data search functions (e.g. Petlab)? The authors discuss the potential for this to be a living data set that expands over time. What plans are there for long-term curation of such an expanding reference dataset? Additionally, interoperability across and linking between data systems is a goal that has been expressed by multiple scientific communities. Careful documentation of data provenance that is recorded in a consistent fashion is one part of achieving this. Unique identifiers like IGSNs for samples and DOIs for papers are another. In volcanology, globally unique IDs exist for volcanic systems and are maintained by the Smithsonian GVP, and these could be incorporated into the dataset. For the Holocene, volcanic eruption and episode IDs also exist.

Analytical and sample processing methodologies are relatively well-described, but the paper could go further. Be sure to include the detection limits for all elements and how these were determined. Additionally, the supplemental spreadsheet file contains a table outlining the LA-ICP-MS method. Please add a similar table for EPMA. Even better, review Abbott et al. (2020, <https://zenodo.org/record/4075613>) “Community Established Best Practice Recommendations for Tephra Studies-from Collection through Analysis” for the documents on methodology reporting. Version 1 of these recommendations was released in May, 2020. Version 2 and some worked examples (e.g. <https://doi.org/10.5281/zenodo.4074289> with EPMA methodology detailed) were released in early October. For EPMA, this includes details such as spectrometer assignments, diffracting crystals, and sequence. As there is not yet a worked example for LA-ICP-MS, the Tephra NZ project could supply the first one for this international

Discussion paper

tephra community effort. Such a stand-alone methods document with DOI could then also be re-usable and could be linked with all papers and datasets that use that same methodology now and in the future.

The paper states that a robust data set with geochemical consistency resulting from consistent methodology is necessary for the optimal use of statistical techniques to correlate tephras. This is because these methods generally do not account for variations resulting from changes in analytical methods over time within a single lab or from biases between different laboratories. Although perhaps ideal, this is not the only approach. Routine use of common reference materials across laboratories can be used to remove most laboratory bias and harmonize datasets, provided that alkali element migration effects (e.g. sodium loss) are sufficiently limited. This is a key reason why the International Focus Group on Tephrochronology and Volcanism (INTAV, recently renamed Commission on Tephrochronology or COT) distributed a set of four reference glasses to more than 25 laboratories for analysis and why a similar effort is currently underway with additional glasses for LA-ICP-MS.

When using the reference glass ATHO-G, it is important to be aware that the published preferred Na₂O concentration of 3.75 wt% (Jochum et al., 2006, Table 13h) is too low. Several analyses with significant sodium loss were not screened out prior to calculating the preferred composition. A majority of newer analyses in the GeoReM database exceed the above reference concentration as do XRF and INAA analyses which are immune to alkali element migration. Kimura et al (2018) also report a concentration of 4.6 by FS-LA-ICP-MS. Together, these data suggest that a Na₂O concentration of 4.3 to 4.6 wt% for ATHO-G is probably more accurate. Using the 3.75 concentration during EPMA standardization or offline correction will bias all results to too low values. Using the same 3.75 concentration when assessing whether Na-loss is sufficiently controlled by an analytical method may also produce an inaccurate interpretation.

Careful removal (but not deletion) of outliers is important before computing summary statistics. The data tables need to be further screened for these. For example, SM

Discussion paper

Table 2 contains obviously problematic trace element analyses like line Kaharoa-P_22 which has elevated Zr. Such points should be set aside and labeled as outliers within the dataset, following recommended practice.

Analyses with very low totals should be considered as outliers, labeled, and set aside. Often, a 90% total (10% water and unanalyzed elements) is used as the threshold for this, but that is not appropriate in all cases. Some maximally hydrated tephtras yield mean totals of 90-91 wt%, and require a somewhat lower cutoff to allow for the range of analytical precision. If a Cl-bearing epoxy is used, elevated Cl concentrations on points that also have low totals indicate that the beam spot is not entirely on tephra glass. Often, these points will compare well to others when normalized to 100% totals, but the Cl will be inaccurate.

I am also concerned about the removal of individual data values that fall below the single analysis detection limits, despite this being commonly applied. It is much better to include the actual data values and also report what the detection limits are. This way, information is not discarded, and each end user can determine what is fit for their own purpose. Fundamentally, analytical techniques like EPMA and ICP-MS are based on signal counting and essentially follow Poisson statistics. Consequently, replicate analyses on a homogeneous material follow a probability distribution. At low enough concentrations, a portion of that distribution will begin to fall below the single analysis detection limit at some selected level of confidence (often chosen as 99% or 3 sigma, but 2 sigma and 1 sigma are valid confidence levels as well). At this point, those specific analyses that fall below the detection limit are no less valid as members of the population than those analyses which fall above the limit. It is therefore completely inappropriate to compute summary statistics like mean, median, mode, or standard deviation when the low end of that population has been removed. Removing those below detection limit values and then computing the mean and standard deviation of those that remain biases the mean to too high a value and reduces the standard deviation, misrepresenting the true precision.

Another community-recommended best practice is to have all tephra analyses and glass standard analyses linked on an analytical session (run) basis. This is because results on common reference glasses are perhaps the best demonstration of analytical quality and because instrument performance can vary from session to session. In SM Table 4, trace element standard analyses are clearly labeled with the individual runs. Please add equivalent information to the other tables for both standards and samples.

Where multiple isotopes are measured for the same element, could these be used in combination rather than reporting concentrations from each with assumed isotopic ratios? (Or alternately use the one less prone to interferences, or an average.)

SM Table 2 puts some EPMA and LA-ICP-MS analyses together on the same line. Presumably this means that both were done on the same shards. If so, state this explicitly.

SM Table 3 Major Standards omits results on VG-A99 despite the paper text indicating that this was run as a secondary (and primary) standard. Please add the data for VG-A99 to the table. This same table lists some individual analyses with surprisingly low Na₂O concentrations for ATHO-G. What is going on with these? Could these represent cases where the electron beam analyzed the same location twice? These problematic results should be set aside and labeled as such but not entirely removed from the table.

SM Table 3 also includes some plots which apparently show results on reference glasses over time. Please add explanation for these. Also, the plots for ATHO-G show some discontinuities and trends that suggest problems with the standardization and/or drift. These results on ATHO-G are worrying. Please explain what is going on here. Do analyses of VG-A99 show the same patterns? The text mentions that offline data reduction was used to correct for variability in the VG-568 primary calibration. Are the ATHO-G results in this table the raw or corrected values?

SM Table 4 – Offset is a percentage. Label it as such for clarity. Relabel 2*Std as 2*StDev for clarity. It may be more useful to compare the offset from reference in ppm

Discussion paper

to the StDev in ppm as a ratio rather than reporting an offset in % of the reference ppm (or do both). This way, if a result is e.g. 3 standard deviations from reference, this would be more readily apparent.

Line 192 – The proximal-distal differences mentioned raise the question of how it would be known that these are the same tephra?

Lines 224- – What was the kV? What is total time for an entire analysis, including spectrometer movement and other instrument overhead?

Lines 232-34 – The text mentions monitoring for drift. Was there drift? How was the drift correction implemented – linear interpolation?

Line 235 – By “applied to all the data” does this mean just all data lines, or all lines and all elements? Where an element is at low concentration on the reference glass (e.g. MnO, MgO in VG-568), the precision may not be sufficient to apply a reliable correction to other analyses. Additionally, such a correction will make little difference where VG-568 is both the primary calibration standard and the offline correction standard for the same element.

Line 237-238 – For older tephra glasses, most of this water can be secondary hydration (water absorbed from the environment post deposition) rather than magmatic. This is acknowledged later in equation 3.

Lines 245-255 – Equations 1 and 2 essentially outline a standards-based (reference material based) normalization using a single standard. This could also be done using a consensus of the three EPMA reference glasses (VG-568, VG-A99, and ATHO-G) for even better consistency. Of course, any bad analyses would have to be set aside prior to computing consensus corrections.

Line 315 – DFA with cross-validation is another way to test this by looking for high rates of misclassification.

Line 321 – “of” instead of “or”

Lines 347-49 – This is perhaps OK as a rough criterion, but precision also scales with concentration due to signal intensity and counting statistics. At lower concentrations, standard deviations will be smaller in wt%, but the relative standard deviation (as a percentage of the analyzed concentration) will be greater. The reverse is true when going to higher concentrations such that a 4x increase in signal intensity corresponds to a relative standard deviation that is reduced by a factor of 1/2 (i.e. scaling with sqrt of total x-rays recorded). So, the standard deviation on a secondary standard only provides an estimate of what should be expected for a homogeneous sample when the concentrations of the same element are similar. Consequently the stated +/- 0.23wt% homogeneity cutoff for Fe would not be appropriate for a sample with a much higher or lower concentration of Fe than the standard.

Line 364 – Crystallization of biotite is not the only way to affect K₂O concentrations. Does the Shane et al (2008) reference provide evidence for biotite fractionation?

Figure 4 – The TiO₂ and MgO appear “quantized” on the plots, probably due to rounding everything to the nearest 0.01 wt% prior to plotting. To avoid artifacts like this, it is often better to carry one extra decimal place.

Line 415 – Perhaps replace “can be used to maintain” with “may exhibit”

Line 453 – Not coincidentally, some of John Westgate’s early work in the 1960 and 1970s (e.g. Westgate & Evans 1978) also used the same three elements.

Line 454 – Perhaps replace “presence” with “inclusion”

Figure 10 – Was Ba not included in the histograms for some reason? Some of the text and later plots point to Ba as a useful discriminator.

Lines 504-505 – Remove “ratios”

Line 606 – Perhaps replace “acts to effectively reduce the variability of” with “exhibits little variability in”

Printer-friendly version

Discussion paper

Line 607 – Perhaps replace “can be used to maintain” with “exemplifies”

Line 610 – Replace “causes the” with “exhibits”

Figure 13 (and supplemental tables) – Where multiple populations are clearly evident as in this figure, it would be useful to clearly identify such populations in the data tables, e.g. as Pop 1, Pop 2. Means and standard deviations should then be computed and reported separately for each major population. Data repositories also need to support archival of such details.

Lines 739-757 – Yes, discovering more tephra layers in marine and lacustrine sections than are known from proximal deposits at potential source volcanoes appears to be common in many volcanic regions. (Multiple examples have been reported for e.g. the Cascades arc too such as at Summer Lake, Oregon.) Therefore, developing more complete records of volcanic events (and also understanding their spatial distribution, timing, and eruptive/dispersal processes) requires the integration of proximal and distal tephra records, ideally into accessible databases.

Tables 1-5 – To facilitate data re-use, provide in the supplemental file spreadsheet versions of all of these tables in addition to the versions embedded within the manuscript.

Table 1 – Relabel easting and northing as longitude and latitude. Also convert to decimal degrees for simpler presentation and easier reuse. Abbott et al. (2020) noted above also contains recommendations regarding reporting of sample details.

Table 2 – This table lists acquisition time, but it does not specify which is peak and which is background or whether one or two backgrounds were measured.
