11

12 **Abstract**

13

14 The late-Pleistocene history of the coastal Cordilleran Ice Sheet remains relatively
15 unstudied compared to chronologies of the Laurentide Ice Sheet. Yet accurate reconstructions of
16 Cordilleran Ice Sheet extent and the timing of ice retreat along the Pacific Coast are essential for
17 paleoclimate modeling, assessing meltwater contribution to the North Pacific, and determining
18 the availability of ice-free land along the coastal Cordilleran Ice Sheet margin for human
19 migration from Beringia into the rest of the Americas. To improve the chronology of Cordilleran
20 Ice Sheet history in the Alexander Archipelago, Alaska, we applied ¹⁰Be and ³⁶Cl dating to
21 boulders and glacially sculpted bedrock in areas previously hypothesized to have remained ice-
22 free throughout the local Last Glacial Maximum (LLGM; 20-17 ka). Results indicate that these
23 sites, and more generally the coastal northern Alexander Archipelago, became ice-free by 15.1 ±
24 0.9 ka (n = 12 boulders; 1 SD). We also provide further age constraints on deglaciation along the
25 southern Alexander Archipelago and combine our new ages with data from two previous studies.
26 We determine that ice retreated from the outer coast of the southern Alexander Archipelago at

27 16.3 ± 0.8 ka (n = 14 boulders; 1 SD). These results collectively indicate that areas above
28 modern sea level that were previously mapped as glacial refugia were covered by ice during the
29 LLGM until between ~16.3 and 15.1 ka. As no evidence was found for ice-free land during the
30 LLGM, our results suggest that previous ice-sheet reconstructions underestimate the regional
31 maximum Cordilleran Ice Sheet extent, and that all ice likely terminated on the continental shelf.
32 Future work should investigate whether presently submerged areas of the continental shelf were
33 ice-free.

34

35 **1 Introduction**

36 The late-Pleistocene history of the coastal Cordilleran Ice Sheet remains relatively
37 unstudied compared to chronologies of the Laurentide Ice Sheet (; Dalton et al., 2020).
38 Cordilleran Ice Sheet margin reconstructions from the Pacific Coast are based largely on
39 qualitative field observations with little chronologic control (Dyke, 2004; Carrara et al., 2007;
40 Dalton et al., 2020). While a few studies have recently generated local ice sheet retreat
41 chronologies from terrestrial locations along the Pacific Coast (Darvill et al., 2018; Lesnek et al.,
42 2018; Lesnek et al., 2020),- there are still large areas of the southeastern Alaskan coastline that
43 lack direct age constraints on deglaciation (Fig. 1). Much of the Northern Hemisphere was
44 covered by continental ice sheets during the global Last Glacial Maximum (GLGM; ~26 – 19
45 ka). Chronologies of northern hemisphere glaciation have revealed that while the Laurentide Ice
46 Sheet and many alpine glaciers worldwide were at their greatest extents during the global Last
47 Glacial Maximum (GLGM; ~26-19 ka), the coastal Cordilleran Ice Sheet and the Puget Lobe
48 reached their maximum size ~20 – 17 cal ka (local Last Glacial Maximum; hereafter LLGM ;
49 Porter and Swanson, 1998; Booth et al., 2003; Praetorius and Mix, 2014; Darvill et al., 2018;

50 Lesnek et al., 2018). Other studies have also explored the Cordilleran Ice Sheet contributions to
51 meltwater pulse 1A (~14.6 ka) following the saddle collapse between the Laurentide Ice Sheet
52 and Cordilleran Ice Sheet (Gregoire et al., 2016; Ivanovic et al., 2017). Improved constraints on
53 Cordilleran Ice Sheet history around the time of meltwater pulse 1A are necessary to elucidate
54 any influences of coastal Cordilleran Ice Sheet configuration and retreat on saddle collapse.
55 Additionally, numerical modeling studies show differing responses of the Cordilleran Ice Sheet
56 to last deglacial climate oscillations, thus highlighting the need for an improved Cordilleran Ice
57 Sheet chronology to bolster model improvement and validation (Tarasov et al., 2012; Seguinot et
58 al., 2014; Gregoire et al., 2016; Seguinot et al., 2016; Ivanovic et al., 2017). Finally, a temporally
59 accurate paleogeographic reconstruction of the coastal Cordilleran Ice Sheet margin is required
60 to assess whether a viable coastal route existed for early Americans migrating from Beringia into
61 the Americas. This route hinges on the presence of ice-free land (refugia) suitable for human
62 habitation during the migration event(s). Earlier mapping efforts and other supporting
63 information indicate areas of potential refugia along the former coastal Cordilleran Ice Sheet
64 margin (Demboski et al., 1999; Cook et al., 2001; Carrara et al., 2003; Carrara et al., 2007;
65 Shafer et al., 2010; Shafer et al., 2011; Hebda et al., 2022).

66 This study has two goals: 1) improve the spatio-temporal patterns of coastal Cordilleran
67 Ice Sheet deglaciation in southeastern Alaska, and 2) assess whether areas of the northern
68 Alexander Archipelago mapped as refugia were ice-free throughout the LLGM and thus
69 available for human habitation (Fig. 2). We report 25 new cosmogenic ^{10}Be exposure ages from
70 boulders and bedrock in the northern Alexander Archipelago – the first exposure ages
71 documenting Cordilleran Ice Sheet retreat from this coastal region. We also report four ^{10}Be and
72 four cosmogenic ^{36}Cl ages from Suemez Island in the southern Alexander Archipelago. Our data

73 constrain the deglaciation of the marine-terminating Cordilleran Ice Sheet margin and expand the
74 overall North Pacific coastal glacial chronology. Our results suggest deglaciation of coastal
75 regions ~15.4 – 14.8 ka in the northern Alexander Archipelago and do not support previous
76 mapping of refugia in areas that are presently above sea level.

77

78 **2 Setting**

79

80 The Alexander Archipelago, southeast Alaska, stretches ~480 km (Fig. 2) along the
81 western coast of British Columbia. The southern part of the archipelago is dominated by Prince
82 of Wales Island and surrounding islands, whereas the northern part encompasses Baranof and
83 Chichagof Islands and a collection of smaller islands. The Alexander Archipelago consists of
84 accreted terranes (Triassic to Cretaceous in age) with quartz-bearing diorite and granodiorite
85 units and notable Eocene-Miocene granitic intrusive complexes (Wilson et al., 2015). Late-
86 Pleistocene volcanic activity on southern Kruzof Island formed the Mt. Edgecumbe volcanic
87 field (Riehle, 1996). Post-LLGM (late-Pleistocene and Holocene) eruptions formed extensive
88 andesite flows on the island and blanketed much of the surrounding area with tephra (Riehle et
89 al., 1984; Riehle et al., 1992; Riehle, 1996). Modern climate of the Alexander Archipelago is
90 dominated by cool, wet summers and mild winters, with perennial heavy rainfall - Sitka (Baranof
91 Island) receives ~2200 mm/yr while Chichagof Island receives over 3300 mm/yr (Ager, 2019;
92 <https://wrcc.dri.edu/summary/Climsmak.html>). Snowfall is minimal at lower elevations, but
93 more substantial in higher elevation areas (<https://wrcc.dri.edu/summary/Climsmak.html>).
94 Glaciers occupy alpine cirques in the Alexander Archipelago (totaling < 150 km²), primarily on
95 Baranof and Chichagof islands (Molnia, 2008). Presently, low-elevation (< 700 m asl) areas of

96 the archipelago are dominated by coniferous rainforests, while alpine tundra exists above the tree
97 line (> 700 m asl; Ager, 2019).

98 Previous mapping shows much, if not all, of southeast Alaska covered by the Cordilleran
99 Ice Sheet during the LLGM and the last deglaciation, with a maximum position likely
100 terminating several kilometers out on the continental shelf of the Gulf of Alaska (Carrara et al.,
101 2007). Ice caps formed atop the Coast Mountains and high massifs of the Alexander Archipelago
102 coalesced and flowed westward to the continental shelf and the Pacific Ocean (Capps, 1932;
103 Mann, 1986; Mann and Hamilton, 1995). Outlet glaciers occupied the present fjord and strait
104 landscape (Carrara et al., 2007). Today, the landscape is strewn with clear indicators of
105 widespread glaciation including deep fjords, glacially sculpted bedrock draped with boulders,
106 and a variety of other glacial landforms, but it remains unclear whether all of southeast Alaska
107 was covered by the Cordilleran Ice Sheet during the LLGM. Some areas of the Alexander
108 Archipelago, presently above sea level, are hypothesized to have been ice-free throughout the
109 LLGM (Carrara et al., 2007). Recent studies using ^{10}Be surface exposure dating of glacial
110 landforms, however, indicate that some of these purported ice-age refugia in the southern
111 Alexander Archipelago were covered by the Cordilleran Ice Sheet during its LLGM advance
112 (Lesnek et al., 2018). Other areas previously mapped as ice age refugia in the northern Alexander
113 Archipelago (Carrara et al., 2007; Dalton et al., 2020) are investigated in this study; if their
114 presence is confirmed with numerical dating techniques, this would be a significant confirmation
115 of the existence of coastal refugia.

116

117

118 **3 Methods**

119

120 **3.1 Boulder and bedrock sampling**

121

122 We collected 29 samples (11 bedrock, 18 boulder) for cosmogenic ^{10}Be surface exposure
123 dating (hereafter ^{10}Be dating) during summer 2018, 2019, and 2020 (Figs. 3 and 4) from several
124 sites in coastal Southeast Alaska, including Suemez ($n = 4$), Baranof ($n = 11$), Biorka ($n = 4$),
125 Kruzof ($n = 4$) and Chichagof ($n = 6$) islands. Our samples range in elevation from ~ 50 to ~ 930
126 m asl; all sites are above the local marine limits of $\sim 10 - 20$ m asl (Baichtal et al., 2021). We
127 preferentially sampled paired sites consisting of stable boulders and neighboring unvegetated
128 bedrock surfaces. This strategy allowed us to assess whether bedrock surfaces contain isotopic
129 inheritance and provides insights into ice-sheet erosion history. In the absence of suitable
130 boulders at a few locations, we sampled bedrock with clear evidence of glacial erosion to
131 mitigate the possibility of ^{10}Be inheritance.

132 We also collected samples from four glacially-transported boulders on the southwestern
133 portion of Suemez Island for ^{36}Cl surface exposure dating during the summer 2019 field season
134 (Figs. 5; 6; Table 2). The boulders consist of non-vesicular olivine basalt of “Tertiary to
135 Quaternary” age (Eberlein et al., 1983).

136 Surface samples were collected from the upper few centimeters of the boulders and
137 bedrock using a handheld angle grinder, hammer, and chisel. We avoided sampling areas of the
138 boulder tops and bedrock surfaces with visible signs of surface erosion (e.g., fractures,
139 weathering pits). We did, however, observe erosional features on the boulders sampled for ^{36}Cl
140 dating. We avoided collecting material from these areas, instead sampling parts of the basaltic
141 boulder tops that showed fresh, unweathered surfaces. We recorded sample locations with a

142 handheld GPS unit or GAIA GPS (both with a vertical uncertainty of ± 5 m) and measured
143 topographic shielding in the field with a clinometer and compass.

144

145 **3.2 ^{10}Be dating**

146

147 We processed samples at the University at Buffalo Cosmogenic Isotope Laboratory
148 following established quartz purification and beryllium extraction procedures (e.g., Corbett et al.,
149 2016). After quartz purification, we dissolved samples in hydrofluoric acid with precisely
150 weighed ^9Be carrier (PRIME Lab 2017.11.17-Be #3/#4; ^9Be concentration of 1074 ± 8 ppm). We
151 isolated, oxidized, and packed beryllium into target cathodes in five different batches for
152 accelerator mass spectrometer (AMS) analysis at PRIME lab at Purdue University. The samples
153 were measured with respect to the 07KNSTD standard ($^{10}\text{Be}/^9\text{Be}$ ratio of 2.85×10^{-12} ; Nishiizumi
154 et al., 2007). We corrected sample ratios using batch-specific blank values between 7.50×10^{-16}
155 and 3.14×10^{-15} . AMS analytical uncertainty ranged from 3.2 to 7.3% with an average value of
156 4.7%.

157 We calculated all ^{10}Be ages using version 3 of the CRONUS-Earth exposure age
158 calculator (hess.ess.washington.edu; Balco et al., 2008; Balco, 2017), using the Arctic production
159 rate (Young et al., 2013) and a time-dependent (L_m) scaling scheme (Lal, 1991).

160

161 **3.3 ^{36}Cl dating**

162

163 All whole rock samples were prepared at the University of New Hampshire Cosmogenic
164 Isotope Laboratory using a modified version of the protocols in Stone et al. (2000) and Licciardi
165 et al. (2008). After samples were crushed, etched in nitric acid, and homogenized, total sample
166 chloride was measured on a ~ 1 g aliquot of rock that was spiked with a small amount of ^{37}Cl -

167 enriched solution (LLNL Spike A; $^{35}\text{Cl}/^{37}\text{Cl} = 0.93$; 1285 ± 3 ppm Cl) and a carrier containing
168 ~ 4000 μg of Br. Cl was extracted as Ag(Cl,Br) following standard procedures and chlorine
169 concentrations were determined through isotope dilution of $^{35}\text{Cl}/^{37}\text{Cl}$ ratios (Faure, 1986). ^{36}Cl
170 was extracted from full rock samples as Ag(Cl,Br) after adding a carrier containing ~ 4800 μg of
171 Br and a natural ratio Cl carrier ($^{35}\text{Cl}/^{37}\text{Cl} = 3.127$; 1436 ± 9 ppm Cl) to increase the size of the
172 final precipitate.

173 $^{35}\text{Cl}/^{37}\text{Cl}$ and $^{36}\text{Cl}/\text{Cl}$ ratios were measured at the Center for Accelerator Mass
174 Spectrometry at Lawrence Livermore National Laboratory. Analytical uncertainty on $^{35}\text{Cl}/^{37}\text{Cl}$
175 measurements ranged from 0.04% to 0.43%; analytical uncertainty on $^{36}\text{Cl}/\text{Cl}$ measurements
176 ranged from 2.12% to 2.87%. Major and trace element analyses were conducted by SGS
177 Minerals Services in Burnaby, British Columbia, Canada. Reported total Cl and ^{36}Cl
178 concentrations are corrected for batch-specific process blanks (Table 2). Analytical data used to
179 determine surface exposure ages are provided in supplementary tables S1 and S2. ^{36}Cl exposure
180 ages were calculated using an in-development version of the CRONUS-Earth ^{36}Cl calculator
181 (http://stoneage.ice-d.org/math/Cl36/v3/v3_Cl36_age_in.html) and Lm scaling (Lal, 1991).

182

183 **3.4 Exposure age calculation considerations**

184

185 We made no corrections for post-glacial elevation changes or snow cover when
186 calculating our ^{10}Be and ^{36}Cl ages. Post-glacial isostatic adjustment results in a time-varying rate
187 of cosmogenic nuclide production (Jones et al., 2019). This effect can be corrected for using
188 comprehensive records of regional emergence constrained by glacial isostatic adjustment models
189 or relative sea-level histories. Hundreds of radiocarbon ages constrain the relative sea level
190 chronology in the Alexander Archipelago; the sites in our study experienced ~ 50 m of relative

191 sea level lowering due to forebulge collapse between ~15 and 10 ka (Baichtal et al., 2021).
192 Corrections for glacial isostatic adjustment history, albeit slightly uncertain given site-to-site
193 differences in elevation history, result in small changes (~1% age decrease), and thus we report
194 our ages without any correction for isostatic adjustment (Tables 1 and 2). Furthermore, changes
195 in air pressure near a retreating ice margin and shifts in air compression above a sample site that
196 experienced elevation change may mitigate any effects of isostatic adjustment on cosmogenic
197 nuclide production, potentially rendering any elevation correction unnecessary (Staiger et al.,
198 2007).

199 Extended periods of thick and dense snow cover can also inhibit ^{10}Be and ^{36}Cl production
200 in a rock surface and lead to erroneously young apparent exposure ages. While modern snowfall
201 reports for lower-elevation areas of the Alexander Archipelago indicate minimal average
202 wintertime snow cover (10 – 20 cm; <https://wrcc.dri.edu/summary/Climsmak.html>), there are no
203 data for higher-elevation areas. Consequently, we cannot report our ages with reliable snow
204 shielding corrections and these exposure dates should be considered minimum ages. However,
205 most of our sites are from low to moderate elevations (<500 m asl; Table 1).

206 Post-depositional weathering and erosion can also affect exposure ages. We observed
207 fresh, unweathered glacially scoured bedrock across all our field sites, indicating minimal post-
208 glacial erosion. We made no corrections for erosion in our age calculations presented within the
209 manuscript text and thus these should be considered minimum ages. For sensitivity purposes, we
210 calculated ages using an erosion rate of 0.3 cm/kyr, similar to erosion rates applied nearby in
211 British Columbia (Menounos et al., 2017). These erosion-corrected ages are between 2% and 7%
212 older and are found in Tables S3 and S4.

213 Both cosmogenic and nucleogenic ^{36}Cl can be present in rock surfaces, and for our
214 surface exposure age calculations we assumed steady state production/decay of nucleogenic ^{36}Cl .
215 Moderate amounts of nucleogenic ^{36}Cl are produced when ^{35}Cl absorbs neutrons released by the
216 decay of U and Th isotopes (Gosse and Phillips, 2001). However, because the formation age of
217 the sampled basalt flow on Suemez Island is loosely constrained to the “Tertiary to Quaternary”
218 (Eberlein et al., 1983), nucleogenic ^{36}Cl production/decay may or may not be in steady state. To
219 assess the sensitivity of our exposure ages to the assumption of steady state nucleogenic ^{36}Cl
220 production, we also calculated exposure ages using a rock formation age of 20 ka, which, given
221 the timing of the LLGM ice advance in Southeast Alaska (Lesnek et al., 2018), is the youngest
222 formation age we might expect for these rocks. Results of this test (Table S3) show that
223 calculated ^{36}Cl ages are relatively insensitive to rock formation age (<1% surface exposure age
224 increase in all cases), which is well within total uncertainty.

225

226 **4 Results**

227

228 We sampled from the summit of a massif at ~410 m asl on south-central Suemez Island
229 (southern Alexander Archipelago) and from a flat bench scattered with boulders on the summit’s
230 flank for ^{10}Be dating (Fig. 6). The two boulders sampled on the bench date to 15.6 ± 0.7
231 (19SEAK-07; Fig. 3) and 15.0 ± 1.1 ka (19SEAK-08; we report all surface exposure ages with 1
232 σ internal uncertainty; Table 1). The summit site featured fresh glacially sculpted bedrock
233 surfaces with a couple boulders resting on the bedrock. A boulder and its adjacent bedrock
234 surface, as a pair, date to 17.4 ± 1.2 (19SEAK-09) and 19.7 ± 1.2 ka (19SEAK-10), respectively
235 (Fig. 3). The three boulders yield a mean age of 16.0 ± 1.2 ka ($n = 3$; 1 SD).

236 On southwestern Suemez Island, we sampled four large boulders for ^{36}Cl dating. The
237 boulders were distributed across a terrain of patchy muskeg with locally outcropping bedrock.
238 Based on reconstructed Cordilleran Ice Sheet flow directions (Lesnek et al., 2020) and boulder
239 composition (supplementary table S2; Eberlein et al., 1983), the boulders were likely plucked
240 from basalt flows present on the southwestern portion of Suemez Island (Brew, 1996). The four
241 basalt boulders from southwestern Suemez Island have ^{36}Cl exposure ages ranging from $12.4 \pm$
242 0.3 to 16.4 ± 0.5 ka (ages are reported at 1σ internal uncertainty; Fig. 5; Table 2). ^{36}Cl surface
243 exposure ages assuming 3 mm/ka of surface erosion and non-steady state nucleogenic ^{36}Cl
244 production are presented in Table S3; for all four samples, changing these parameters results in
245 calculated surface exposure ages $<2\%$ higher than those presented in the main text.

246 We collected samples from four sites (Baranof Sites A – D; Fig. 7) on the ocean-facing
247 side of Baranof Island, northern Alexander Archipelago. Here, we chose our helicopter ground
248 stops in an area previously mapped as ice-free throughout the LLGM (Carrara et al., 2007; Fig.
249 7). Evidence for glacial sculpting of bedrock surfaces is clear; glacial grooves, striations and
250 chatter marks are present at all sites, and the bedrock surfaces, in places, are topped by perched
251 boulders (Fig. 3). Field evidence of recent glaciation, including relatively unweathered chatter
252 marks, grooves, and striations, contradicts prior mapping of these areas being ice-free during the
253 LLGM.

254 Baranof Site A is a large, unforested area of bedrock outcrops composed of several
255 smaller ridges. Here, we sampled two bedrock surfaces – one from the stoss side of a bedrock
256 outcrop (19SEAK-18; Fig. 3) and one from the top surface of a nearby bedrock patch (19SEAK-
257 19) – which date to 21.7 ± 0.9 and 28.0 ± 1.1 ka, respectively. A boulder sampled adjacent to
258 bedrock (sample 19SEAK-18) yielded an exposure age of 16.9 ± 0.8 ka (19SEAK-17). A second

259 boulder sample from this site dates to 14.4 ± 0.7 ka (19SEAK-20; Fig. 3). At Baranof Site B – a
260 raised bedrock knob – we sampled two boulders and one bedrock surface. The two boulders have
261 ^{10}Be ages of 15.1 ± 0.6 ka (19SEAK-23; Fig. 3), 14.4 ± 0.7 ka (19SEAK-21); the bedrock sample
262 has a ^{10}Be age of 14.4 ± 0.6 ka (19SEAK-22). Baranof Site C is a high ridge between the ocean
263 and a U-shaped valley with abundant bedrock outcrops and few boulders. Here, a boulder yielded
264 an exposure age of 16.3 ± 0.6 ka (19SEAK-24; Fig. 3) whereas a bedrock surface dates to $15.7 \pm$
265 0.6 ka (19SEAK-25). Finally, Baranof Site D is a small bedrock ridge between two peaks with
266 massive stoss and lee features. At this site, we collected samples from two quartz veins in the
267 bedrock, which have exposure ages of 18.2 ± 0.7 (19SEAK-26; Fig. 3) and 20.2 ± 0.8 ka
268 (19SEAK-27). Because the sites are all in relatively close proximity and from similar elevations
269 (50 – 160 m asl), we treat the samples as having experienced the same glacial history, and thus
270 should belong to a single age population. Collectively, boulder samples yield a mean age of 15.4
271 ± 1.1 ka ($n = 5$; 1 SD) with no obvious outliers, whereas the bedrock samples exhibit more scatter
272 and are mostly older than the mean boulder age (Fig. 9).

273 Biorka Island, a small island off the western coast of central Baranof Island, was initially
274 mapped as ice-covered throughout the LLGM (Dyke, 2004). Here, there are numerous ~1 m tall
275 boulders that rise above the surrounding vegetation and rest on ice-sculpted bedrock. Vegetation
276 and sediments mostly obscure underlying bedrock surfaces, and thus we only collected samples
277 from boulders at this sampling site. Our four boulder samples yielded exposure ages of $15.3 \pm$
278 0.5 (18JB005; Fig. 4), 14.9 ± 0.6 (18JB006), 15.4 ± 0.5 (18JB007; Fig. 4), and 13.7 ± 0.5 ka
279 (18JB008), with a mean of 14.8 ± 0.8 ka ($n = 4$; 1 SD; Fig. 8).

280 We visited a summit ridge at 545 – 560 m asl on the western, ocean-facing side of
281 northwestern Kruzof Island, previously mapped as ice-free throughout the LGM (Dalton et al.,

282 2020). There, we found many large stable boulders and exposed patches of glacially sculpted
283 bedrock between vegetation exhibiting glacial grooves and chatter marks. Here, we sampled
284 three large boulders ($> 2 \times 2 \times 1$ m), which date to 14.9 ± 0.8 (20SEAK-07; Fig. 4), 14.9 ± 0.9
285 (20SEAK-12) and 14.6 ± 0.8 ka (20SEAK-13; Fig. 4), yielding a mean age of 14.8 ± 0.2 ka ($n =$
286 3 ; 1 SD; Fig. 8). A bedrock surface at this site dates to 13.4 ± 1.0 ka (20SEAK-10; Fig. 4) and
287 sits ~ 10 m below and ~ 10 m away from the boulder that dated to 14.6 ± 0.8 ka (20SEAK-13).

288 We collected samples from three sites on Chichagof Island (Chichagof Sites A – C; Fig.
289 8). Unlike our other sampling locations which are on the ocean-facing, western sides of the
290 archipelago, the Chichagof Island sites are all located inland. We visited these sites to determine
291 the timing of ice retreat inland and to complement the findings of a previous study that
292 documented ice withdrawal in the central and eastern Alexander Archipelago (Lesnek et al.,
293 2020). Chichagof Island is notable for its relative lack of boulders – consequently, the boulders
294 sampled here are smaller than those at other sites. While many bedrock outcrops featured smooth
295 surfaces indicative of glacial erosion, we did not observe clear striations or chatter marks. At site
296 A, a bedrock bench, ^{10}Be ages from two small, perched boulders are 12.7 ± 0.7 (20SEAK-15; 0.5
297 $\times 0.3 \times 0.3$ m; 476 m asl; Fig. 4) and 9.0 ± 0.6 ka (20SEAK-16; $0.5 \times 0.4 \times 0.3$ m; 473 m asl). A
298 quartz vein sampled from bedrock outcrop at this site has an exposure age of 15.3 ± 0.7 ka
299 (20SEAK-14). Site B is a series of bedrock ridges, and a single boulder yields an exposure age of
300 12.4 ± 0.9 ka (20SEAK-18; 817 m asl; Fig. 4), while an adjacent bedrock surface dates to $14.1 \pm$
301 0.7 ka (20SEAK-19; 816 m asl). Finally, site C is at the summit of a massif and one bedrock
302 knob sampled here has an exposure age of 17.7 ± 0.8 ka (20SEAK-22; 779 m asl; Fig. 4).

303

304

305 **5 Discussion**

306

307 **5.1 Bedrock ^{10}Be ages**

308

309 We sampled large and stable boulders in addition to bedrock surfaces with clear evidence
310 of glacial erosion (e.g., striations, chatter marks) with the goal of providing optimal constraints
311 on deglaciation. Sampling bedrock surfaces also allows us to better understand the subglacial
312 erosion regime across the Alexander Archipelago, potentially yielding information about the
313 duration of ice cover, the amount of subglacial erosion, and the likelihood of boulders containing
314 inheritance.

315 Bedrock exposure ages are older than the mean boulder exposure ages by two SD or
316 greater on Sumez Island (19SEAK-10) and Baranof sites A (19SEAK-18, 19SEAK-19) and D
317 (19SEAK26, 19SEAK-27). At Chichagof site A the bedrock exposure age (20SEAK-14) is ~ 4.5
318 kyr older than the mean boulder age, but still within two standard deviations, perhaps due to the
319 large spread in boulder ages resulting in larger standard deviations. At Chichagof site B, the
320 single boulder ^{10}Be age (20SEAK-18) post-dates the single bedrock age by ~ 1.7 kyr. In general,
321 bedrock data reported here are consistent with bedrock ^{10}Be ages from Warren and Baker islands
322 that are older (by more than 2 SD) than mean boulder ages (Lesnek et al., 2018). Bedrock ages
323 may be erroneously older due to ^{10}Be inheritance if ice sheet erosion was insufficient to remove
324 the ~ 2 m of rock required to remove most of the previous ^{10}Be inventory. Studies from British
325 Columbia (Darvill et al., 2018) and Washington (Briner and Swanson, 1998) also report
326 cosmogenic nuclide inheritance in bedrock from other areas covered by the Cordilleran Ice
327 Sheet. In our field area, the short-lived nature of the overriding event (~ 3 kyr; Lesnek et al.,
328 2018) may also contribute to the lack of significant glacial erosion. Finally, traces of inheritance

329 may be present in bedrock, perhaps even boulders, in ice-sheet-distal sites like these that are
330 overrun by ice during extremely brief portions of the Quaternary (Briner et al., 2016).

331 In some cases, boulder-bedrock pairs have similar exposure ages (on southern Baranof
332 and Suemez islands), suggesting our bedrock ages are unaffected by ^{10}Be inheritance at these
333 sites. On Kruzof Island, a bedrock patch yields an exposure age that is younger (by more than 2
334 σ) than the mean age of the surrounding boulders. Potential cover by snow, sediment, or
335 vegetation is thought to have caused anomalously young ages elsewhere in the Alexander
336 Archipelago (Lesnek et al., 2020) and may also explain this ^{10}Be age from our bedrock site on
337 Kruzof Island.

338 Bedrock exposure ages vary greatly (by as much as ~ 14 kyr) between the various
339 sampling locations on Baranof Island and up to 6 kyr on Suemez Island (Lesnek et al., 2018).
340 The Alexander Archipelago is characterized by impressive relief (deep fjords, high peaks), and
341 thus, sub-glacial erosion rates clearly varied greatly across Suemez and Baranof islands where
342 sampling locations are $\sim 2 - 6$ km apart. Differing bedrock ^{10}Be ages from the same sampling
343 locales confirm this inference, reflecting variable sub-glacial erosion rates even within ~ 100 m of
344 each other. Some samples may have been collected in areas dominated by glacial abrasion,
345 whereas other samples might be from surfaces dominated by quarrying, and thus, this variability
346 could reflect varying subglacial processes on a local scale.

347 Because bedrock exposure ages from the coastal Alexander Archipelago (this study;
348 Lesnek et al., 2018) do not consistently pre-date, match, or post-date exposure ages from
349 adjacent boulders, we refrain from including bedrock-based ^{10}Be ages in our mean deglaciation
350 age calculations (Figs. 9; 10). This negates biases when choosing which bedrock ages “match”
351 nearby erratic ages and allows us to eliminate any concern over inheritance or post-ice retreat

352 cover of these bedrock surfaces. While bedrock ages, especially when paired with boulder ages,
353 are useful for identifying spatially variable subglacial erosion processes and issues with past
354 cover and inheritance, they do not appear to provide reliable age constraints on the timing of
355 deglaciation in the Alexander Archipelago due to the inconsistencies between bedrock and
356 boulder ages. In light of this, we also recalculate relevant mean ages from Lesnek et al. (2018;
357 2020) using solely boulder ^{10}Be ages to update these other regional chronologies.

358

359 **5.2 ^{10}Be chronology incompatible with mapped Cordilleran Ice Sheet extent**

360

361 We targeted areas of the northern Alexander Archipelago mapped as ice-free by previous
362 studies to determine whether these areas were LLGM refugia. The most recent coastal
363 Cordilleran Ice Sheet reconstructions show significant portions of the northern Alexander
364 Archipelago as remaining ice-free throughout the LLGM (Fig. 2), with ice terminating close to
365 the present shoreline – not on the continental shelf (Dalton et al., 2020; Lesnek et al., 2020). Our
366 data, however, indicate that at least some of these areas previously mapped as refugia
367 (southwestern Baranof and Kruzof islands) were covered by ice, and deglaciated around 15.4 –
368 14.8 ka. Our new evidence thus suggests that ice extended onto the continental shelf during the
369 LLGM, as in the southern Alexander Archipelago (Lesnek et al., 2018). These discrepancies
370 between previously mapped ice extents and those implied by our new exposure ages highlight
371 the need to develop deglaciation chronologies elsewhere along the Cordilleran Ice Sheet coastal
372 margin to provide updated mapping around the north Pacific.

373

374

375 **5.3 Cordilleran Ice Sheet retreat across the Alexander Archipelago**

376
377 Mean boulder ^{10}Be exposure ages from Suemez Island in this study and Lesnek et al.
378 (2018), $16. \pm 1.2$ ka ($n = 3$ boulders; 1 SD) and 16.6 ± 0.8 ka ($n = 3$ boulders; 1 SD),
379 respectively, overlap within 1 standard deviation (Figs. 6; 9). However, three of the boulder ^{36}Cl
380 ages from southwestern Suemez Island do not overlap with the ^{10}Be ages at 1 standard deviation
381 (Figs. 6; 9). We attribute this scatter to post-depositional surface erosion of the basaltic boulders
382 (i.e., those dated with ^{36}Cl) in excess of 3 mm/ka. Although we targeted areas of the boulder
383 tops with no obvious signs of erosion, given the maritime climate of Southeast Alaska it is
384 possible that the original, glacially eroded boulder surfaces have been weathered. Surface erosion
385 of rocks with low concentrations of native Cl (supplementary table S2), where the primary ^{36}Cl
386 production pathway is Ca-spallation (Marrero et al., 2016), results in exposure ages that are
387 erroneously young. Thus, we interpret the oldest ^{36}Cl exposure age (16.4 ± 0.5 ka; 19SEAK-02)
388 as the closest constraint on deglaciation at that site. This ^{36}Cl age overlaps with the ^{10}Be ages
389 from elsewhere on Suemez Island; we combine them and calculate a new, boulder-based mean
390 deglaciation age of 16.3 ± 0.8 ka ($n = 10$ boulders; 1 SD) for Suemez Island.

391 We group together three of our sampling locations in the northern Alexander Archipelago
392 that are ocean-facing: Kruzof, Biorka, and southern Baranof islands. As the Cordilleran Ice Sheet
393 retreated from the continental shelf inland, these were the first areas presently above sea level to
394 become ice-free. We calculate a mean ^{10}Be boulder age of 15.1 ± 0.9 ka ($n = 12$ boulders; 1 SD)
395 for the coastal northern Alexander Archipelago.

396 There are limited data from elsewhere in the northern Alexander Archipelago that
397 constrain the timing of deglaciation. A basal pollen concentrate-based radiocarbon age from
398 Hummingbird Lake (Fig. 7), southwestern Baranof Island dates to 15.0 ± 0.2 cal ka, in

399 agreement with the ^{10}Be ages presented here and that collectively indicate coastal Baranof Island
400 was deglaciated prior to ~ 15 ka (Ager, 2019). Additionally, tephra layers from Mt. Edgecumbe
401 on Kruzof Island are dated to 13.1 ka (Riehle et al., 1992; Beget et al., 1998), and blanket many
402 of the surrounding islands, suggesting that these areas were ice-free by then.

403 All three sample sites on Chichagof Island (Sites A – C) are not ocean-adjacent and
404 characterized by a general lack of boulders. The boulders present were much smaller and shorter
405 (< 0.5 m high) than boulders sampled elsewhere across the Alexander Archipelago – we chose to
406 sample these despite their size to provide minimum ages for deglaciation and to compare with
407 available radiocarbon constraints. The ages of these boulders fall between 9.0 ± 0.6 and $12.7 \pm$
408 0.7 ka and are thus younger than other age constraints for deglaciation on Chichagof Island;
409 radiocarbon ages on shells from raised marine terraces on Chichagof Island date back to $14.2 \pm$
410 0.6 cal ka suggesting that the island was ice-free by this time (Baichtal et al., 2021). Smaller
411 boulders are more susceptible to cover (whether snow, vegetation, or sediment), and may thus
412 yield anomalously young ^{10}Be ages. While a lack of large boulders found on Chichagof Island
413 makes it difficult to ascertain the timing of deglaciation, regional glacial and sea-level history
414 suggests Chichagof Island was deglaciated between 15.1 (when the coastal area deglaciated) and
415 14.2 cal ka (the age of shells in raised marine deposits). Therefore, the boulders dated here likely
416 have anomalously young exposure ages.

417 Our mean ^{10}Be age of 15.1 ± 0.9 ka ($n = 12$ boulders; 1 SD) from all sites along the
418 coastal portion of the northern Alexander Archipelago fits with the few other regional
419 deglaciation constraints (Fig. 2) and overlaps within one standard deviation with the mean
420 boulder exposure age from the southern Alexander Archipelago of 16.3 ± 0.8 ka ($n = 13$
421 boulders; 1 σ ; this study; Lesnek et al., 2018; Lesnek et al., 2020). While mean ages from the

422 northern and southern Alexander Archipelago overlap within one standard deviation, it is
423 possible that these areas deglaciated at slightly different times as these various sampling sites
424 happened to become ice-free. Furthermore, local ice caps formed and radiated from massifs on
425 Chichagof, Baranof, and Prince of Wales islands during the LLGM (Capps, 1932; Mann and
426 Hamilton, 1995; Lesnek et al., 2020). These local ice caps served as a local ice source for the
427 Alexander Archipelago and their locations and flow patterns may have led to some parts of the
428 archipelago becoming ice-free before others. Thus, we present a range of deglaciation across the
429 coastal Alexander Archipelago from between 16.3 ± 0.8 ka and 15.1 ± 0.9 ka

430 Ice retreat across the Alexander Archipelago is also registered in marine sediments off
431 the former coastal Cordilleran Ice Sheet margin. Several marine sedimentary records (cores
432 EW0408-26JC, EW0408-66JC, EW0408-85JC) extending back to ~ 18.5 cal ka show the
433 presence of IRD beginning ~ 18.5 ka, peaking at 17.5 – 16.5 ka and ceasing at 14.8 ka, reflecting
434 a final retreat of marine-terminating ice (Praetorius and Mix, 2014). Furthermore, these IRD data
435 record fluctuating but relatively elevated calving spanning 18.5 to 14.8 ka, perhaps indicating
436 steady retreat punctuated by periods of accelerated melting.

437 Tephra from Mt. Edgecumbe (Kruzof Island) found in core EW0408-26JC is interpreted
438 to have been deposited in a submarine environment, suggesting that this core site was ice-free by
439 14.6 ka (Praetorius et al., 2016). Records of a subsequent eruption dated to ~ 13.1 cal ka from
440 marine sediments in Sitka Sound (core EW0408-40JC) indicate that this area (between Baranof
441 and Kruzof islands) must have been ice-free by this time (Addison et al., 2010). Finally, ^{14}C ages
442 from mollusks found in a diamicton layer along the Gastineau Channel date to ~ 13.8 cal ka,
443 reflecting the beginning of deglaciation near the mainland (Miller, 1973; we calibrate all
444 uncalibrated ^{14}C ages with CALIB 8.2; Stuiver et al., 2021).

445 **5.4 Chronologies of Cordilleran Ice Sheet deglaciation across the North Pacific**

446
447 Radiocarbon ages from the Cordilleran Ice Sheet margin reflect ice advance from ~20 –
448 17 ka, near the end of the GLGM at 19 ka. Ages from mammalian fossils in Shuká Káa on Prince
449 of Wales Island indicate Cordilleran Ice Sheet advance ~20 ka in the Alexander Archipelago
450 (Lesnek et al., 2018). Directly south of the Alexander Archipelago, on eastern Graham Island
451 (Haida Gwaii) initial ice advance is dated to 24.1 – 22.5 cal ka with a ¹⁴C date from a twig
452 underlying till (Blaise et al., 1990; Mathewes and Clague, 2017). Along the southwestern
453 Cordilleran Ice Sheet margin, ice reached its maximum extent until ~17.0 ka in the Puget Sound
454 area (Porter and Swanson, 1998).

455 Glacier chronologies from the northeastern Pacific coastline also reflect post-GLGM
456 retreat. On Sanak Island, tephra near the bottom of a lake sediment core dates deglaciation before
457 ~15.9 ka, broadly synchronous with Cordilleran Ice Sheet withdrawal in the Alexander
458 Archipelago (Misarti et al., 2012). On Kodiak Island, final LLGM retreat dates to ~15.7 cal ka,
459 as marked by a ¹⁴C age above glacio-tectonically altered sediments (Mann and Peteet, 1994).
460 Directly north of the Alexander Archipelago, a ¹⁴C age from a log found within the Finger
461 Glacier lateral moraine provides a minimum age of deglaciation at ~14.6 cal ka (Mann, 1986).
462 Radiocarbon ages from a marine sediment core in Dixon Entrance date maximum Cordilleran Ice
463 Sheet extent to before ~16.1 cal ka and retreat beginning before ~15.3 cal ka (Barrie and
464 Conway, 1999). A marine sediment record from Vancouver Sound similarly dates maximum ice
465 extent to 18.5 ka and retreat of the Cordilleran Ice Sheet onto the mainland by 16.4 ka (Blaise et
466 al., 1990). Quaternary sediments on eastern Graham Island indicate the Cordilleran Ice Sheet was
467 retreating by 17.8 cal ka (Blaise et al., 1990). Notably, ¹⁰Be ages on Calvert Island suggest ice

468 retreated off the continental shelf at ~18 ka, pre-dating ice withdrawal onto land in the Alexander
469 Archipelago (Darvill et al., 2018).

470 Marine sediment cores are interpreted to show ice retreat across the coastal northeastern
471 Pacific. A marine sediment core (SO202-27-6) from the Gulf of Alaska captures a decrease in
472 sea surface salinity ~16 ka, interpreted to reflect increased meltwater from the Cordilleran Ice
473 Sheet margin (Maier et al., 2018). Another marine sediment core (EW0408-85JC) recovered off
474 the coast of southern Alaska records a decrease in glacial-margin sediment accumulation at 16.9
475 ka as ice stagnated or began to retreat. (Davies et al., 2011). Reductions in salinity captured by
476 planktonic $\delta^{18}\text{O}$ in this core at ~16.7 ka are interpreted as an increase in meltwater input from
477 retreating glaciers. A transition from ice-proximal to laminated hemipelagic sediments at ~14.8
478 ka marks glacier retreat off the continental shelf and onto land. Off the coast of Alaska, a marine
479 sediment core records a peak of IRD deposition peaking between 18 and 17 ka, interpreted as the
480 retreat of marine-terminating margins of the Cordilleran Ice Sheet (Walczak et al., 2020).
481 Additionally, another core from off Vancouver Island (MD02-2496) captures IRD deposition
482 between ~17.0 and ~16.2 cal ka – indicating rapid regional deglaciation – and a minor IRD event
483 at ~14.7 cal ka (Cosma et al., 2008).

484 Our new data showing ice retreat at 15.1 ± 0.9 ka from the northern Alexander
485 Archipelago, along with ages of deglaciation from the southern Alexander Archipelago ($16.3 \pm$
486 0.8 ka; this study; Lesnek et al., 2018), are broadly synchronous with previously published ice
487 retreat chronologies for the marine-terminating Cordilleran Ice Sheet margin elsewhere along the
488 northeast Pacific Coast. However, while our chronology only documents deglaciation, it provides
489 further evidence of a delayed LLGM across the coastal Cordilleran Ice Sheet compared to the

490 GLGM maximum extents of alpine glaciers in mainland Alaska (Briner et al., 2017), parts of
491 southern Alaska (Reger et al., 1996), and the Laurentide Ice Sheet (Dalton et al., 2020).

492

493 **5.5 Paleoclimate Records from the North Pacific**

494

495 Several paleoclimate records from around the North Pacific span our interval of
496 Cordilleran Ice Sheet deglaciation in the Alexander Archipelago. A combined diatom
497 assemblage- and alkenone-derived record of sea surface temperatures (SSTs) from the Bering
498 Sea (Core 51JPC), records perennial sea ice from ~22.5 ka (beginning of record) to 17 ka, and
499 increased SSTs beginning ~16.9 ka before a notable shift back to annual sea ice ~16.7 ka
500 (Caissie et al., 2010). In the northern Gulf of Alaska (Core EW0408-85JC), $\delta^{18}\text{O}$ data document
501 increasing SSTs at 16.7 ka and again at ~14.7 ka (Davies et al., 2011). Alkenone-inferred paleo-
502 SST reconstructions from this same core show the lowest SSTs (~5 °C) circa 17.0 ka, with
503 increased SSTs beginning ~16.5 ka, and a rapid ~3 - 4 °C rise in SSTs from 15.2 to 14.7 ka
504 (Praetorius et al., 2015). Alkenone-inferred SST and $\delta^{18}\text{O}$ records from the Gulf of Alaska also
505 record increased SSTs of ~3°C at 14.7 ka (cores EW0408-26JC, EW0408-66JC; Praetorius et al.,
506 2016). Off Vancouver Island, Mg/Ca temperature reconstructions from subsurface-dwelling *N.*
507 *pachyderma* indicate two stages of warming of ~2 °C at 17.2 – 16 ka, and a further ~3 °C 15.5 –
508 14.0 ka, while surface-dwelling *G. bulloides* record a 3 °C SST increase from 15.0 – 14.0 ka
509 (core MD02-2496; Taylor et al., 2014), all within the uncertainty of coastal Alexander
510 Archipelago ice retreat. Alkenone SST reconstructions from another nearby core (core JT96-09)
511 also indicates a 4 °C increase in SST at ~14.7 ka (Kienast and McKay, 2001).

512 There are few terrestrial paleoclimate data that span the last deglacial period from
513 southeast Alaska and coastal British Columbia. Cordilleran ice cover until ~15 ka across much of

514 the region impeded the preservation of many terrestrial records – however, there are limited ice
515 core, speleothem, and lake records that date back to early regional deglaciation or prior. A
516 growth hiatus in a speleothem from El Capitan Cave (southern Alexander Archipelago) spanning
517 ~41.5 to ~13.4 ka suggests the cave was either overridden by the Cordilleran Ice Sheet,
518 experienced permafrost conditions and a mean annual air temperature $< 0\text{ }^{\circ}\text{C}$, or lacked drip
519 water (Wilcox et al., 2019). The youngest date also serves as a minimum limit on deglaciation, as
520 the area was thawed by ~13.4 ka. However, El Capitan Cave is ~60 km inland of the outermost
521 coastal region and therefore may have still experienced these conditions while the outer coast
522 deglaciated. At Hummingbird Lake, southwestern Baranof Island, pollen records indicate *Pinus*
523 *contorta* dominated from ~15.2 ka to 14 ka, which is interpreted to represent *Pinus contorta*
524 response to the beginnings of Gulf of Alaska ocean warming at ~16.5 ka (Praetorius et al., 2015;
525 Ager, 2019). This record suggests increased air temperatures around deglaciation of the
526 Alexander Archipelago between 16.3 ± 0.8 ka and 15.1 ± 0.9 ka.

527

528 **5.6 Implications for early human migration**

529

530 Several studies have scrutinized potential areas of LLGM glacial refugia in the Alexander
531 Archipelago through a human migration perspective (Carrara et al., 2007; Lesnek et al., 2018),
532 building off similar approaches from elsewhere in the North Pacific (e.g., Warner et al., 1982;
533 Mann and Peteet, 1994; Misarti et al., 2012). Our study focused on southern Baranof and Kruzof
534 islands because previous mapping suggested that parts of these areas were ice-free throughout
535 the LLGM (Carrara et al., 2003; Carrara et al., 2007). However, our ^{10}Be ages from southern
536 Baranof Island indicate these areas were glaciated throughout the LLGM and not available for

537 human habitation between ~20 ka and ~15.4 ka. Our exposure ages from Kruzof Island also
538 suggest this area was not ice free until ~14.8 ka.

539 These results indicate that some of the last major unevaluated areas of possible refugia
540 presently above sea-level were covered by ice during the LLGM. At its maximum extent, ice
541 likely extended onto the then-exposed continental shelf. Ice occupation of the continental shelf –
542 or at least parts of the shelf – off the Alexander Archipelago was relatively brief, from ~20.0 to
543 ~16.0 ka (Lesnek et al., 2018). Areas of the continental shelf would have been above modern sea
544 level during this time and until ~11 – 8 ka, when sea level neared modern levels in the Alexander
545 Archipelago (Baichtal et al., 2021). At a minimum, ice lobes would have existed within the
546 major shelf troughs (e.g., Chatham Strait), likely crossing the entire shelf at these locations; at a
547 maximum, the entire continental shelf may have been occupied by ice from ~20 to ~16 ka.
548 Whether portions of the shelf remained ice-free during the LLGM is unknown, but it is possible.
549 Based on the immediate colonization of *Pinus* at 15.2 ka in Hummingbird Lake and as early as
550 ~15.4 ka on Pleasant Island, there were likely ice-free areas on the shelf throughout the LLGM
551 (Hansen and Engstrom, 1996; Ager, 2019).

552

553 **6 Conclusions**

554

555 We conclude that several areas in southeast Alaska previously mapped as ice-free
556 through the LLGM were covered by ice until between ~16.3 and ~15.1 ka. ¹⁰Be ages from
557 boulders suggest that the northern coastal Alexander Archipelago deglaciated at 15.1 ± 0.9 ka,
558 while ¹⁰Be and ³⁶Cl ages date ice retreat in the southern portion at 16.3 ± 0.8 ka, following a
559 LLGM that began after ~20 ka (Lesnek et al., 2018; Lesnek et al., 2020) The timing of
560 deglaciation in the Alexander Archipelago is similar to some other sites around the Cordilleran

561 Ice Sheet coastal margin (e.g., Mann and Peteet, 1994; Misarti et al., 2012), but later than other
562 locations (e.g., Darvill et al., 2018). Notably, the deglaciation in southeast Alaska is later than in
563 mainland Alaska and Kodiak and Sanak Islands, Alaska (Fig. 1), where records are more aligned
564 with the GLGM. The timing of deglaciation in the Alexander Archipelago is broadly
565 synchronous with regional records of local ocean and air temperature increases. We also found
566 that anomalously old ^{10}Be ages of bedrock surfaces are likely due to inheritance caused by
567 insufficient ice sheet erosion, and thus urge caution when using ages from bedrock surfaces as
568 direct constraints on ice retreat without additional boulder ages along the coastal margins of the
569 Cordilleran Ice Sheet.

570 Our data indicate that previous mapping of the coastal Cordilleran Ice Sheet can be
571 spatially and temporally improved. We suggest that ice likely extended out on the continental
572 shelf along the Alexander Archipelago. We are increasingly confident that areas of the coastal
573 Cordilleran Ice Sheet previously mapped as ice-free throughout the LLGM were in fact covered
574 by ice, and that refugia, if any existed, would have been located on the exposed continental shelf.
575 Although more logistically challenging, subsequent studies should evaluate the existence of
576 LLGM refugia in the Alexander Archipelago by focusing on the previously exposed continental
577 shelf. Special attention should be given to the northern Alexander Archipelago where ice masses
578 were fed by local ice caps and thus may not have been as extensive, as opposed to elsewhere in
579 the northeastern Pacific where ice was sourced from the main body of the Cordilleran Ice Sheet.

580

581 **7 Acknowledgements**

582

583 We acknowledge that these samples were collected on the ancestral lands of the Tlingit
584 and that the University at Buffalo exists on the land of the Seneca. These peoples are the

585 traditional caretakers of these lands and we give thanks for the opportunity to exist and work on
586 lands that are rightfully theirs. We thank the Tongass National Forest for assistance with
587 permitting and logistics. We thank Corey Krabbenhoft, Joseph Tulenko and Karlee Prince for
588 field assistance and Joseph Tulenko and Chris Sbarra for lab assistance. We also thank PRIME
589 Lab for ^{10}Be measurements and Lawrence Livermore National Laboratory for ^{36}Cl
590 measurements. This research was funded by NSF (award # 1854550), the National Geographic
591 Society (award # 57989R-19), a Geological Society of America Student Research Grant (grant
592 number 13631) funded by NSF (award # 1949901), the Alaska Geological Society, and the Mark
593 Diamond Research Fund of the Graduate Student Association at the University at Buffalo, the
594 State University of New York.

596 **8 Author Contributions**

597 JPB designed the study framework and acquired the majority of grant funds. CKW acquired
598 supplementary funding for fieldwork and lab analyses. CKW, JPB, JFB, and AJL collected
599 samples in the field. CKW conducted ^{10}Be work and AJL and JML performed ^{36}Cl chemistry.
600 CKW, JPB, AJL, and JML analyzed sample data and calculated ages. All authors were involved
601 in interpreting the data. CKW wrote the first draft of the manuscript; all authors provided
602 substantial input. CKW and AJL created figures and tables.

^a Elevations and positions were recorded with a Garmin handheld GPS receiver (~5 m vertical uncertainty) or GAIA GPS (~5 m vertical uncertainty).

^b AMS results from PRIME Lab are standardized to 07KNSTD (Nishiizumi et al., 2007); ratios are blank corrected and shown at 1 SD uncertainty.

^c ^{10}Be ages reported with one σ internal uncertainties; external uncertainties in parentheses; calculated with CRONUS-Earth calculator v. 3 (Balco et al., 2008) using the Arctic production rate (Young et al., 2013) or global production rate (Borchers et al., 2016) and Lm scaling.

^a Elevations and positions were recorded with a Garmin handheld GPS receiver (~5 m vertical uncertainty) or GAIA GPS (~5 m vertical uncertainty).

^b The ^{37}Cl -enriched spike was made at Lawrence Livermore National Laboratory. Its Cl concentration is 1285 ppm and its $^{35}\text{Cl}/^{37}\text{Cl}$ ratio is 0.93.

^c The natural Cl carrier was made by dissolving Weeks Island Halite in deionized water at the University of New Hampshire. Its Cl concentration is 1436 ± 9 ppm and its $^{35}\text{Cl}/^{37}\text{Cl}$ ratio is 3.127.

^d Uncertainties on $^{35}\text{Cl}/^{37}\text{Cl}$ and $^{36}\text{Cl}/\text{Cl}$ ratios and exposure ages represent propagated 1 σ analytical uncertainties only

^e Sample ^{36}Cl concentrations are corrected for ^{36}Cl contributed by process blank CLBLK-26

^f Exposure ages are presented at 1 σ internal uncertainty; external uncertainty shown in parentheses. Ages were calculated with the CRONUSEarth ^{36}Cl calculator (http://stoneage.ice-d.org/math/Cl36/v3/v3_Cl36_age_in.html) and Lm scaling (Lal, 1991) assuming no surface erosion and steady state nucleogenic ^{36}Cl production.

^h Aliquot for stable Cl measurements processed with CLBLK-AQ8

ⁱ Aliquot for stable Cl measurements processed with CLBLK-AQ4

Figure 6: ^{10}Be and ^{36}Cl ages from samples collected on Suemez on island: red and yellow dots mark sampling site from this study, blue dot marks sampling site from Lesnek et al.(2018). Bold ages are from boulders; plain ages are from bedrock. All ^{10}Be and ^{36}Cl ages reported with 1σ internal uncertainty.

Figure 7: ^{10}Be ages from sampling sites on southern Baranof Island. Bold ages are from boulders; plain ages are from bedrock. All ages are reported with 1σ internal error. Cordilleran Ice Sheet LLGM extent after Carrara et al. (2007).

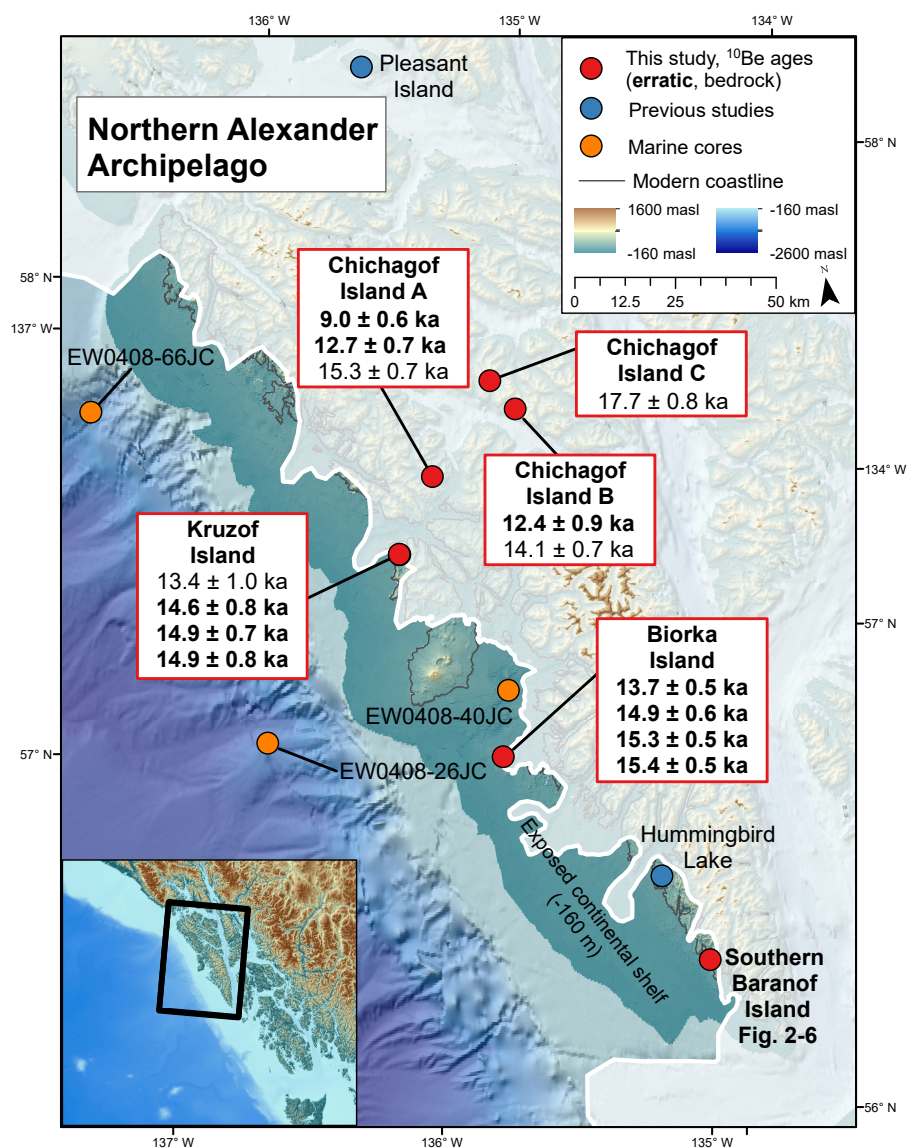

Figure 8: ^{10}Be ages from sampling sites in the northern Alexander Archipelago. All ages are reported with 1σ internal error. Bold ages are from boulders; plain ages are from bedrock.. LLGM Cordilleran Ice Sheet extent after Lesnek et al. (2020). Exposed continental shelf at -160 m below modern sea level Baichtal et al. (in press). Yellow dots show location of relevant marine sediment cores: EW0408-66JC and EW0408-26JC (Praetorius and Mix, 2014; Praetorius et al., 2016) and EW0408-40JC (Addison et al., 2010). Blue dots show locations of relevant terrestrial study sites: Pleasant Island (Hansen and Engstrom, 1996) and Hummingbird Lake (Ager, 2019).

Figure 9: Relative probably plots of bedrock (red) and boulder (blue) ^{10}Be and ^{36}Cl boulder (yellow) ages from this study calculated with 1σ internal uncertainty. bo. = boulder, br. = bedrock. All ages shown are mean ages from only boulders at each sample site reported with 1 SD unless noted. Cumulative plots represent all bold lines - transparent lines were not included in their calculation. ^aAverage of all ^{10}Be boulder ages and oldest ^{36}Cl boulder age with 1 SD. ^bAverage of all ^{10}Be boulder ages (this study and Lesnek et al., 2018) and oldest ^{36}Cl boulder age (this study). ^cOne old outlier at 28.0 ± 1.1 ka not shown.

Figure 10: A) Proxy Northern Hemisphere temperature anomaly relative to early Holocene with 1σ error (Shakun et al., 2012). B) Eustatic sea-level curve (Spratt and Lisiecki, 2016). C) Gulf of Alaska surface salinity $\delta^{18}\text{O}$ record (Core SO202-27-6; Maier et al., 2018). D) U^k_{37} temperature reconstruction from off the coast of the Alexander Archipelago (Cores EW0408-26JC, EW0408-66JC; Praetorius et al., 2016). E) Ice rafted debris record from off Vancouver Island (Core MD02-2496; Cosma et al., 2008). F) & G) Meanboulder ^{10}Be ages from the coastal Alexander Archipelago, with 1σ r (this study; Lesnek et al., 2018; 2020).
