### **Abstract**

The late-Pleistocene history of the coastal Cordilleran Ice Sheet (CIS) remains relatively  
15 unstudied compared to chronologies of the Laurentide Ice Sheet. Yet accurate reconstructions of  
CIS extent and timing of ice retreat along the Pacific Coast are essential for a variety of reasons  
including paleoclimate modeling, assessing meltwater contribution to the North Pacific, and  
determining the availability of ice-free land along the coastal CIS margin for human migration  
from Beringia into the Americas. To improve the chronology of CIS history in the Alexander  
20 Archipelago, Alaska, we applied <sup>10</sup>Be and <sup>36</sup>Cl dating to boulders and glacially sculpted bedrock  
outcrops in areas previously hypothesized to have remained ice-free throughout the local Last  
Glacial Maximum (ILGM; 20-17 ka). Results indicate that these sites, and more generally the  
coastal northern Alexander Archipelago, became ice-free by  $15.1 \pm 0.9$  ka ( $n = 12$  boulders; 1  
SD). We also provide further age constraints on deglaciation along the southern Alexander  
25 Archipelago and combine our new ages with data from two previous studies. We determine that  
ice retreated from the outer coast of the southern Alexander Archipelago at  $16.3 \pm 0.8$  ka ( $n = 14$

boulders; 1 SD). These results collectively indicate that areas above modern sea level that were previously mapped as glacial refugia were covered by ice during the ILGM until between ~16.3 and 15.1 ka. As no evidence was found for ice-free land during the ILGM, our results suggest  
30 that previous ice-sheet reconstructions underestimate the regional maximum CIS extent, and that all ice likely terminated on the continental shelf. Future work should investigate whether presently submerged areas of the continental shelf were ice-free.

## 1 Introduction

35 The late-Pleistocene history of the coastal Cordilleran Ice Sheet (CIS) remains relatively unstudied compared to chronologies of the Laurentide Ice Sheet (LIS; Dalton et al., 2020). CIS margin reconstructions from the Pacific Coast are based largely on qualitative field observations with little chronologic control (Dyke, 2004; Carrara et al., 2007; Dalton et al., 2020). While a few studies have recently generated local ice sheet retreat chronologies from terrestrial locations  
40 along the Pacific Coast (Darvill et al., 2018; Lesnek et al., 2018; Lesnek et al., 2020), there remain vast stretches of the Pacific coastline that lack direct age constraints on deglaciation (Fig. 1). Accurate reconstructions of CIS extent and the timing of ice retreat along the Pacific Coast are essential for paleoclimate modeling, assessing glacial meltwater contributions to the North Pacific and subsequent Northern Hemisphere climate impacts, predicting future mass loss  
45 from other marine-terminating ice sheets, and determining whether a coastal route from Beringia into the Americas was viable for humans during southward migration.

Much of the Northern Hemisphere was covered by continental ice sheets during the global Last Glacial Maximum (gLGM; ~26 – 19 ka). While the LIS and many alpine glaciers worldwide were at their greatest extents during this time, the coastal CIS and the Puget Lobe

50 reached maximum size ~20 – 17 ka (local Last Glacial Maximum; hereafter ILGM; Porter and Swanson, 1998; Booth et al., 2003; Praetorius and Mix, 2014; Lesnek et al., 2018).

Accurate constraints of CIS deglaciation are necessary to investigate research topics across numerous disciplines. Recent studies have explored the CIS contributions to meltwater pulse 1A (~14.6 ka) following the saddle collapse between the LIS and CIS (Gregoire et al., 2016; Ivanovic et al., 2017). Improved constraints on CIS history around meltwater pulse 1A are necessary to elucidate any influences coastal CIS configuration and retreat had on saddle collapse. Additionally, numerical modeling studies show differing responses of the CIS to last deglacial climate oscillations, thus highlighting the need for an improved CIS chronology to bolster model improvement and validation (Tarasov et al., 2012; Seguinot et al., 2014; Gregoire et al., 2016; Seguinot et al., 2016; Ivanovic et al., 2017). Finally, a temporally accurate paleogeographic reconstruction of the coastal CIS margin is required to assess whether a viable coastal route existed for early Americans migrating from Beringia into the Americas. This route hinges on the presence of ice-free land (refugia) suitable for human habitation throughout the ILGM. Earlier mapping efforts and other supporting information indicate areas of potential refugia along the former coastal CIS margin (Demboski et al., 1999; Cook et al., 2001; Carrara et al., 2003; Carrara et al., 2007; Shafer et al., 2010; Shafer et al., 2011).

This study has two goals: 1) to improve the spatio-temporal patterns of coastal CIS deglaciation in southeastern Alaska (SE AK), and 2) to assess whether areas of the northern Alexander Archipelago mapped as refugia were ice-free throughout the ILGM and thus available for human habitation (Fig. 2). We report 25 new cosmogenic  $^{10}\text{Be}$  exposure ages from boulders and bedrock from the northern Alexander Archipelago – the first exposure ages documenting CIS retreat from the coastal northern Alexander Archipelago. We also report four  $^{10}\text{Be}$  and four

cosmogenic  $^{36}\text{Cl}$  ages from Suemez Island in the southern Alexander Archipelago. Our data constrain the deglaciation of the marine-terminating CIS margin while expanding the overall  
75 North Pacific coastal glacial chronology. Our results suggest deglaciation of coastal regions  
~15.4 – 14.8 ka in the northern Alexander Archipelago and do not support previous mapping that shows refugia in areas that are presently above sea level.

## 2 Setting

80

The Alexander Archipelago, SE AK, stretches ~480 km (Fig. 2) along the western coast of British Columbia. The southern part of the archipelago is dominated by Prince of Wales Island and surrounding islands, whereas the northern part encompasses Baranof and Chichagof Islands and a collection of smaller islands. The Alexander Archipelago consists of accreted terranes  
85 (Cretaceous to Triassic in age) with quartz-bearing diorite and granodiorite units and notable Eocene-Miocene granitic intrusive complexes (Wilson et al., 2015). Late-Pleistocene volcanic activity on southern Kruzof Island formed the Mt. Edgecumbe volcanic field (Riehle, 1996). Post-ILGM (late-Pleistocene and Holocene) eruptions formed extensive andesite flows on the island and blanketed much of the surrounding area with tephra (Riehle et al., 1984; Riehle et al.,  
90 1992; Riehle, 1996). Modern climate of the Alexander Archipelago is dominated by cool, wet summers and mild winters, with perennial heavy rainfall (Ager, 2019). Snowfall is minimal at lower elevations, but more substantial in higher elevation areas (<https://wrcc.dri.edu/summary/Climsmak.html>). Glaciers occupy alpine cirques in the Alexander Archipelago (totaling < 150 km<sup>2</sup>), primarily on Baranof and Chichagof islands (Molnia, 2008). Presently, low-elevation (<

95 700 m asl) areas of the archipelago are dominated by coniferous rain forests, while alpine tundra exists above the tree line ( $> 700$  m asl; Ager, 2019).

Previous mapping shows much, if not all, of SE AK covered by the CIS during the ILGM and the last deglaciation, with a maximum position likely terminating several kilometers out on the continental shelf of the Gulf of Alaska (Carrara et al., 2007). Ice caps formed atop the Coast  
100 Mountains and high massifs of the Alexander Archipelago, coalesced, and flowed westward to the continental shelf and the Pacific Ocean (Capps, 1932; Mann, 1986; Mann and Hamilton, 1995). Outlet glaciers occupied the present fjord and strait landscape (Carrara et al., 2007). Today, the landscape is strewn with clear indicators of widespread glaciation (deep fjords, glacially sculpted bedrock draped with boulders, and a variety of other glacial landforms), but it  
105 remains unclear whether all of SE AK was covered by the CIS during the ILGM. Some areas of the Alexander Archipelago, presently above sea level, were mapped as ice-free throughout the ILGM (Carrara et al., 2007). Recent studies using  $^{10}\text{Be}$  surface exposure dating of glacial landforms, however, indicate that some of these areas of hypothesized ice-age refugia in the southern Alexander Archipelago were covered by the CIS during its ILGM advance (Lesnek et  
110 al., 2018). Other areas previously interpreted as ice age refugia in the northern Alexander Archipelago are investigated in this study.

Knowledge of the late-Pleistocene glacial history of the southern Alexander Archipelago and areas of coastal British Columbia has recently improved. Radiocarbon-dated marine sediments indicate that the CIS reached its maximum extent sometime between  $\sim 25$  and  $\sim 18$  ka  
115 in SE AK (Mann and Hamilton, 1995; Barrie and Conway, 1999; Praetorius and Mix, 2014). Later work, combining  $^{14}\text{C}$  dating of terrestrial macrofossils from Shuká Káa and  $^{10}\text{Be}$  dating of glacial erratics and sculpted bedrock demonstrated maximum CIS extent in the Prince of Wales

Island region between ~19.8 and ~17 ka, followed by rapid retreat between ~17 and 15 ka, leading to ice-free inner fjords and sounds by 15 ka and a transition to a primarily land-terminating ice sheet thereafter (Lesnek et al., 2018; Lesnek et al., 2020; Baichtal et al., in press).  
120 A speleothem from Prince of Wales records a growth hiatus from  $41.5 \pm 0.2$  ka to  $13.4 \pm 0.2$  ka, interpreted as the presence of permafrost and/or the CIS over the cave, and thus mean annual air temperatures below  $0^{\circ}\text{C}$  during this time (Wilcox et al., 2019). About 400 km to the south in central coastal British Columbia, CIS deglaciation began ~18.2 ka on Calvert Island, within  
125 maximum (~27 ka) and minimum (~16 ka) terrestrial macrofossil  $^{14}\text{C}$  age constraints on nearby Haida Gwaii (Warner et al., 1982; Mathewes and Clague, 2017). Records of alkenone-derived sea surface temperatures (SSTs), ice-rafted debris (IRD), and  $\delta^{18}\text{O}$  from marine sediment cores in the Gulf of Alaska show two periods of increased temperatures and concurrent meltwater input at ~17 ka and ~14.7 ka (Kienast and McKay, 2001; Cosma et al., 2008; Davies et al., 2011;  
130 Taylor et al., 2014; Maier et al., 2018). The retreat of the CIS in southeastern Alaska and coastal British Columbia is attributed primarily to this ocean warming and eustatic sea level rise at the CIS margins beyond the zero-meter isobase, potentially exacerbated by atmospheric temperature and precipitation changes (Lesnek et al., 2020).

Although recent CIS chronologies from the southern Alexander Archipelago provide new  
135 insight into the regional glacial history, few direct ages for CIS deglaciation are available elsewhere along the coastal CIS, including the northern Alexander Archipelago. Basal radiocarbon ages from Hummingbird Lake on southwestern Baranof Island indicate regional CIS deglaciation prior to 15.0 ka (Ager, 2019). Tephra overlying IRD in Sitka Sound and draped across Baranof and several other islands is dated to 14.6 ka and provides a minimum constraint  
140 on the retreat of marine-terminating margins onto land (Praetorius et al., 2016). Previous

mapping (Carrara et al., 2007; Dalton et al., 2020) shows ice-free coastal terrain currently above sea level during the ILGM; if confirmed with numerical dating techniques, this would be a significant confirmation of the existence of coastal refugia.

## 145 **3 Methods**

### **3.1 Boulder and bedrock sampling**

We collected 29 samples for cosmogenic  $^{10}\text{Be}$  surface exposure dating (hereafter  $^{10}\text{Be}$  dating) during summer 2018, 2019, and 2020 (Figs. 3 and 4). These included 11 bedrock and 18 boulder samples from Suemez ( $n = 4$ ), Baranof ( $n = 11$ ), Biorka ( $n = 4$ ), Kruzof ( $n = 4$ ) and Chichagof ( $n = 6$ ) islands. Our samples ranged in elevation from ~50 to ~930 m asl; all sites are above the local marine limits of ~10 – 20 m asl (Baichtal et al., in press). We preferentially sampled paired sites consisting of stable boulders and neighboring unvegetated bedrock surfaces. This allows us to assess whether bedrock surfaces contain isotopic inheritance, which helps interpret our suite of  $^{10}\text{Be}$  ages and provides insights into ice-sheet erosion history. In the absence of suitable boulders at a few locations, we sampled bedrock with clear evidence of glacial erosion to mitigate the possibility of  $^{10}\text{Be}$  inheritance.

We also collected samples from four glacially-transported boulders on the southwestern portion of Suemez Island for  $^{36}\text{Cl}$  surface exposure dating during the summer 2019 field season (Figs. 5; 6; Table 2). The boulders consist of non-vesicular olivine basalt of a similar composition to a Pleistocene-aged basalt flow mapped on southwestern Suemez Island by Eberlein et al. (1983).

Surface samples were collected from the upper few centimeters of the boulders and  
165 bedrock using a handheld angle grinder, hammer, and chisel. We avoided sampling areas of the  
boulder tops and bedrock surfaces with visible signs of surface erosion (e.g., fractures,  
weathering pits). However, we did observe these features elsewhere on the boulders sampled for  
 $^{36}\text{Cl}$  dating. We recorded sample locations with a handheld GPS unit or GAIA GPS (both with a  
vertical uncertainty of  $\pm 5$  m) and measured topographic shielding in the field with a clinometer  
170 and compass.

### 3.2 $^{10}\text{Be}$ dating

We processed samples at the University at Buffalo Cosmogenic Isotope Laboratory  
175 following established quartz purification and beryllium extraction procedures (e.g., Corbett et al.,  
2016). After quartz purification, we dissolved samples in hydrofluoric acid with precisely  
weighed  $^9\text{Be}$  carrier (PRIME Lab 2017.11.17-Be #3/#4;  $^9\text{Be}$  concentration of  $1074 \pm 8$  ppm). We  
isolated, oxidized, and packed beryllium into target cathodes in five different batches for  
accelerator mass spectrometer (AMS) analysis at PRIME lab at Purdue University. The samples  
180 were measured with respect to the 07KNSTD standard ( $^{10}\text{Be}/^9\text{Be}$  ratio of  $2.85 \times 10^{-12}$ ; Nishiizumi  
et al., 2007). We corrected sample ratios using batch-specific blank values between  $7.50 \times 10^{-16}$   
and  $3.14 \times 10^{-15}$ . AMS analytical uncertainty ranged from 3.2 to 7.3% with an average value of  
4.7%.

We calculated all  $^{10}\text{Be}$  ages using version 3 of the CRONUS-Earth exposure age  
185 calculator (hess.ess.washington.edu; Balco et al., 2008; Balco, 2017), using the Arctic production  
rate (Young et al., 2013) and a time-dependent (Lm) scaling scheme (Lal, 1991).

### 3.3 $^{36}\text{Cl}$ dating

190 All whole rock samples were prepared at the University of New Hampshire Cosmogenic Isotope Laboratory using a modified version of the protocols in Stone et al. (2000) and Licciardi et al. (2008). Samples were crushed to a 125-250  $\mu\text{m}$  grain size, then rinsed in deionized water and leached in a weak  $\text{HNO}_3$  solution to remove organic material. Each leached sample was homogenized using a riffle splitter and a  $\sim 1.2$  g aliquot was removed to determine total sample

195 chloride. The aliquots were spiked with a small amount of  $^{37}\text{Cl}$ -enriched solution (LLNL Spike A;  $^{35}\text{Cl}/^{37}\text{Cl} = 0.93$ ;  $1285 \pm 3$  ppm Cl). Aliquots also received  $\sim 4000$   $\mu\text{g}$  of Br (in the form of  $\text{NH}_4\text{Br}$ ), which served to increase the size of the final precipitate. The aliquots were then dissolved in a solution of HF and  $\text{HNO}_3$ . After dissolution, fluoride compounds were removed by centrifuging.  $\text{Ag}(\text{Cl}+\text{Br})$  was precipitated through the addition of  $\text{AgNO}_3$ . The  $\text{Ag}(\text{Cl}+\text{Br})$

200 precipitates were recovered, rinsed, and packed into stainless steel cathodes for measurement of  $^{35}\text{Cl}/^{37}\text{Cl}$  ratios, which were used to calculate total sample chloride by isotope dilution methods (Faure, 1986). For the  $^{36}\text{Cl}$  extraction, samples received a small amount of natural-ratio Cl carrier ( $^{35}\text{Cl}/^{37}\text{Cl} = 3.127$ ;  $1436 \pm 9$  ppm Cl) to ensure consistent Cl loads within the analytical batch. All samples received  $\sim 4800$   $\mu\text{g}$  of Br. The samples were dissolved in an HF- $\text{HNO}_3$  solution and

205 insoluble fluorides were removed through centrifuging.  $\text{Ag}(\text{Cl}+\text{Br})$  was precipitated by adding  $\text{AgNO}_3$ . The  $\text{Ag}(\text{Cl}+\text{Br})$  precipitates were recovered and dissolved in a solution of  $\text{NH}_4\text{OH}$ . To remove  $^{36}\text{S}$ , an isobar of  $^{36}\text{Cl}$ ,  $\text{BaNO}_3$  was added to the solutions to precipitate  $\text{BaSO}_4$ . The purified  $\text{Ag}(\text{Cl}+\text{Br})$  was precipitated by acidifying the solutions with  $\text{HNO}_3$  and adding  $\text{AgNO}_3$ . The  $\text{Ag}(\text{Cl}+\text{Br})$  precipitates were then recovered, rinsed, and dried.

210  $^{35}\text{Cl}/^{37}\text{Cl}$  and  $^{36}\text{Cl}/\text{Cl}$  ratios were measured at the Center for Accelerator Mass Spectrometry at Lawrence Livermore National Laboratory. Analytical uncertainty on  $^{35}\text{Cl}/^{37}\text{Cl}$

measurements ranged from 0.04% to 0.43%; analytical uncertainty on  $^{36}\text{Cl}/\text{Cl}$  measurements ranged from 2.12% to 2.87%. Major and trace element analyses were conducted by SGS Minerals Services in Burnaby, British Columbia, Canada. Reported total Cl and  $^{36}\text{Cl}$  concentrations are corrected for process blanks (Table 2). Analytical data used to determine surface exposure ages are provided in supplementary tables S1 and S2.  $^{36}\text{Cl}$  exposure ages were calculated using an in-development version of the CRONUS-Earth  $^{36}\text{Cl}$  calculator ([http://stoneage.ice-d.org/math/Cl36/v3/v3\\_Cl36\\_age\\_in.html](http://stoneage.ice-d.org/math/Cl36/v3/v3_Cl36_age_in.html)) and Lm scaling (Lal, 1991). For comparison,  $^{36}\text{Cl}$  ages calculated using version 2.1 of CRONUScalc (Marrero et al., 2016a) are included in supplementary table S3.

### 3.4 Exposure age calculation considerations

We made no corrections for post-glacial elevation changes, post-depositional erosion, or snow cover when calculating our  $^{10}\text{Be}$  and  $^{36}\text{Cl}$  ages. Post-glacial isostatic adjustment results in a time-varying rate of cosmogenic nuclide production (Jones et al., 2019). This can be corrected for using comprehensive records of regional emergence constrained by glacier isostatic adjustment models or relative sea level histories. Hundreds of radiocarbon ages constrain the relative sea level chronology in the Alexander Archipelago; the sites in our study experienced ~50 m of relative sea level lowering due to forebulge collapse between ~15 and 10 ka (Baichtal et al., in press). Corrections for this, albeit slightly uncertain given site-to-site differences in elevation history, result in small changes (~1% age decrease), and thus we report our ages without any correction for isostatic adjustment (Tables 1 and 2). Furthermore, changes in air pressure near a retreating ice margin and shifts in air compression above a sample site that experienced elevation change may mitigate any effects of isostatic adjustment on cosmogenic

nuclide production, potentially rendering any elevation correction unnecessary (Staiger et al., 2007).

Post-depositional weathering and erosion can also affect exposure ages. We observed fresh, unweathered glacially scoured bedrock across all our field sites, indicating minimal post-  
240 glacial erosion. Therefore, we made no corrections for erosion in our age calculations.

Extended periods of thick and dense snow cover can also inhibit  $^{10}\text{Be}$  and  $^{36}\text{Cl}$  production in a rock surface and lead to erroneously young apparent exposure ages. While modern snowfall reports for lower-elevation areas of the Alexander Archipelago indicate minimal average wintertime snow cover (10 – 20 cm; <https://wrcc.dri.edu/summary/Climsmak.html>), there are no  
245 data for higher-elevation areas. Consequently, we cannot report our ages with reliable snow shielding corrections and these exposure dates should be considered minimum ages. However, most of our sites are from low to moderate elevations (<500 m asl; Table 1).

#### 4 Results

250

We sampled from the summit of a massif at ~410 m asl on south-central Suemez Island (southern Alexander Archipelago) and from a flat bench scattered with boulders on the summit's flank for  $^{10}\text{Be}$  dating (Fig. 6). The two boulders sampled on the bench date to  $15.6 \pm 0.7$  (19SEAK-07; Fig. 3) and  $15.0 \pm 1.1$  ka (19SEAK-08; we report all surface exposure ages with 1  
255  $\sigma$  internal uncertainty; Table 1.). The summit site featured fresh glacially sculpted bedrock surfaces with a couple boulders resting on the bedrock. A boulder and its adjacent bedrock surface, as a pair, date to  $17.4 \pm 1.2$  (19SEAK-09) and  $19.7 \pm 1.2$  ka (19SEAK-10), respectively (Fig. 3). The three boulders yield a mean age of  $16.0 \pm 1.2$  ka ( $n = 3$ ; 1 SD).

On southwestern Suemez Island, we sampled four large boulders for  $^{36}\text{Cl}$  dating. The  
260 boulders were distributed across a terrain of patchy muskeg with locally outcropping bedrock.  
Based on reconstructed CIS flow directions (Lesnek et al., 2020) and boulder composition  
(supplementary table S2; Eberlein et al., 1983), the boulders were likely plucked from basalt  
flows present on the southwestern portion of Suemez Island (Brew, 1996). The four basalt  
boulders from southwestern Suemez Island have  $^{36}\text{Cl}$  exposure ages ranging from  $12.5 \pm 1.1$  to  
265  $16.6 \pm 1.6$  ka (ages are reported at  $1 \sigma$  internal uncertainty; Fig. 5; Table 2).

We collected samples from four sites (Baranof Sites A – D; Fig. 7) on the ocean-facing  
side of Baranof Island, northern Alexander Archipelago. Here, we chose our helicopter ground  
stops in an area previously mapped as ice-free throughout the ILGM (Carrara et al., 2007; Fig.  
7). Evidence for glacial sculpting of bedrock surfaces is clear; glacial grooves, striations and  
270 chatter marks are present at all sites, and the bedrock surfaces, in places, are topped by perched  
boulders (Fig. 3). Field evidence of recent glaciation, including relatively unweathered chatter  
marks, grooves, and striations, contradicts prior mapping of these areas being ice-free during the  
ILGM.

Baranof Site A is a large, unforested area of bedrock outcrops composed of several  
275 smaller ridges. Here, we sampled two bedrock surfaces – one from the stoss side of a bedrock  
outcrop (19SEAK-18; Fig. 3) and one from the top surface of a nearby bedrock patch (19SEAK-  
19) – which date to  $21.7 \pm 0.9$  and  $28.0 \pm 1.1$  ka, respectively. A boulder sampled adjacent to  
bedrock (sample 19SEAK-18) yielded an exposure age of  $16.9 \pm 0.8$  ka (19SEAK-17). A second  
boulder sample from this stop dates to  $14.4 \pm 0.7$  ka (19SEAK-20; Fig. 3). At Baranof Site B – a  
280 raised bedrock knob – we sampled two boulders and one bedrock surface. The two boulders have  
 $^{10}\text{Be}$  ages of  $15.1 \pm 0.6$  ka (19SEAK-23; Fig. 3),  $14.4 \pm 0.7$  ka (19SEAK-21); the bedrock

samples has a  $^{10}\text{Be}$  age of  $14.4 \pm 0.6$  ka (19SEAK-22). Baranof Site C is a high ridge between the ocean and a U-shaped valley with abundant bedrock outcrops and few boulders. Here, a boulder yielded an exposure age of  $16.3 \pm 0.6$  ka (19SEAK-24; Fig. 3) whereas a bedrock surface dates to 285  $15.7 \pm 0.6$  ka (19SEAK-25). Finally, Baranof Site D is a small bedrock ridge between two peaks with massive stoss and lee features. At this site, we collected samples from two quartz veins in the bedrock, which have exposure ages of  $18.2 \pm 0.7$  (19SEAK-26; Fig. 3) and  $20.2 \pm 0.8$  ka (19SEAK-27). Because the sites are all in relatively close proximity and from similar elevations (50 – 160 m asl), we treat the samples as having experienced the same glacial history, and thus 290 should belong to a single age population. Collectively, boulder samples yield a mean age of  $15.4 \pm 1.1$  ka ( $n = 5$ ; 1 SD) with no obvious outliers, whereas the bedrock samples exhibit more scatter and are mostly older than the mean boulder age (Fig. 9).

Biorka Island, a small island off the western coast of central Baranof Island, was initially mapped as ice-covered throughout the ILGM (Dyke, 2004). Here, there are numerous ~1 m tall 295 boulders that rise above the surrounding vegetation and rest on ice-sculpted bedrock. Vegetation and sediments mostly obscure underlying bedrock surfaces, and thus we only collected samples from boulders at this sampling site. Our four boulder samples yielded exposure ages of  $15.3 \pm 0.5$  (18JB005; Fig. 4),  $14.9 \pm 0.6$  (18JB006),  $15.4 \pm 0.5$  (18JB007; Fig. 4), and  $13.7 \pm 0.5$  ka (18JB008), with a mean of  $14.8 \pm 0.8$  ka ( $n = 4$ ; 1 SD; Fig. 8).

300 We visited a summit ridge at 545 – 560 m asl on the western, ocean-facing side of northwestern Kruzof Island, previously mapped as ice-free throughout the LGM (Dalton et al., 2020). There, we found many large stable boulders and exposed patches of glacially sculpted bedrock between vegetation exhibiting glacial grooves and chatter marks. Here, we sampled three large boulders ( $> 2 \times 2 \times 1$  m), which date to  $14.9 \pm 0.8$  (20SEAK-07; Fig. 4),  $14.9 \pm 0.9$

305 (20SEAK-12) and  $14.6 \pm 0.8$  ka (20SEAK-13; Fig. 4), yielding a mean age of  $14.8 \pm 0.2$  ka ( $n =$   
3; 1 SD; Fig. 8). A bedrock surface at this site dates to  $13.4 \pm 1.0$  ka (20SEAK-10; Fig. 4) and  
sits  $\sim 10$  m below and  $\sim 10$  m away from the boulder that dated to  $14.6 \pm 0.8$  ka (20SEAK-13).

We collected samples from three sites on Chichagof Island (Chichagof Sites A – C; Fig.  
8). Unlike our other sampling locations which are on the ocean-facing, western sides of the  
310 archipelago, the Chichagof Island sites are all located inland. We visited these sites to determine  
the timing of ice retreat inland and to complement the findings of a previous study that  
documented ice withdrawal in the central and eastern Alexander Archipelago (Lesnek et al.,  
2020). Chichagof Island is notable for its relative lack of boulders – consequently, the boulders  
sampled here are smaller than those at other sites. While many bedrock outcrops featured smooth  
315 surfaces indicative of glacial erosion, we did not observe clear striations or chatter marks. At site  
A, a bedrock bench,  $^{10}\text{Be}$  ages from two small, perched boulders are  $12.7 \pm 0.7$  (20SEAK-15;  $0.5$   
 $\times 0.3 \times 0.3$  m; 476 m asl; Fig. 4) and  $9.0 \pm 0.6$  ka (20SEAK-16;  $0.5 \times 0.4 \times 0.3$  m; 473 m asl). A  
quartz vein sampled from bedrock outcrop at this site has an exposure age of  $15.3 \pm 0.7$  ka  
(20SEAK-14). Site B is a series of bedrock ridges, and a single boulder yields an exposure age of  
320  $12.4 \pm 0.9$  ka (20SEAK-18; 817 m asl; Fig. 4), while an adjacent bedrock surface dates to  $14.1 \pm$   
 $0.7$  ka (20SEAK-19; 816 m asl). Finally, site C is at the summit of a massif and one bedrock  
knob sampled here has an exposure age of  $17.7 \pm 0.8$  ka (20SEAK-22; 779 m asl; Fig. 4).

## 5 Discussion

325

### 5.1 Bedrock $^{10}\text{Be}$ ages

We sampled large and stable boulders in addition to bedrock surfaces with clear evidence of  
glacial erosion (e.g., striations, chatter marks) with the goal of providing optimal constraints on

330 deglaciation. Sampling bedrock surfaces also allows us to better understand the subglacial erosion regime across the Alexander Archipelago, potentially yielding information about the duration of ice cover, the amount of subglacial erosion, and the likelihood of boulders containing inheritance.

Bedrock exposure ages are older than the mean boulder exposure ages by two SD or  
335 greater on Suemez Island (19SEAK-10) and Baranof sites A (19SEAK-18, 19SEAK-19) and D (19SEAK26, 19SEAK-27). At Chichagof site A the bedrock exposure age (20SEAK-14) is ~4.5 kyr older than the mean boulder age, but still within two standard deviations, perhaps due to the large spread in boulder ages resulting in larger standard deviations. At Chichagof site B, the single boulder  $^{10}\text{Be}$  age (20SEAK-18) post-dates the single bedrock age by ~1.7 kyr. In general,  
340 bedrock data reported here are consistent with bedrock  $^{10}\text{Be}$  ages from Warren and Baker islands that are older (by more than 2 SD) than mean boulder ages (Lesnek et al., 2018). Bedrock ages may be erroneously older due to  $^{10}\text{Be}$  inheritance if ice sheet erosion was insufficient to remove the ~2 m of rock required to remove most of the previous  $^{10}\text{Be}$  inventory. Studies from British Columbia (Darvill et al., 2018) and Washington (Briner and Swanson, 1998) also report  
345 cosmogenic nuclide inheritance in bedrock from other areas covered by the CIS. In our field area, the short-lived nature of the overriding event (~3 kyr; Lesnek et al., 2018) may also contribute to the lack of significant glacial erosion. Finally, traces of inheritance may be present in bedrock, perhaps even boulders, in ice-sheet-distal sites like these that are overrun by ice during extremely brief portions of the Quaternary (Briner et al., 2016).

350 In some cases, boulder-bedrock pairs have similar exposure ages (on southern Baranof and Suemez islands), suggesting our bedrock ages are unaffected by  $^{10}\text{Be}$  inheritance at these sites. On Kruzof Island, a bedrock patch yields an exposure age that is younger (by more than 2

σ) than the mean age of the surrounding boulders. Potential cover by snow, sediment, or  
vegetation is thought to have caused anomalously young ages elsewhere in the Alexander  
355 Archipelago (Lesnek et al., 2020) and may also explain this  $^{10}\text{Be}$  age from our bedrock site on  
Kruzof Island.

Bedrock exposure ages vary greatly (by as much as ~14 kyr) between the various  
sampling locations on Baranof Island and up to 6 kyr on Suemez Island (Lesnek et al., 2018).  
The Alexander Archipelago is characterized by impressive relief (deep fjords, high peaks), and  
360 thus, sub-glacial erosion rates clearly varied greatly across Suemez and Baranof islands where  
sampling locations are ~2 – 6 km apart. Differing bedrock  $^{10}\text{Be}$  ages from the same sampling  
locales confirm this, reflecting variable sub-glacial erosion rates even within ~100 m of each  
other. Some samples may have been collected in areas dominated by glacial abrasion, whereas  
other samples might be from surfaces dominated by quarrying, and thus, this variability could  
365 reflect varying subglacial processes on a local scale.

Because bedrock exposure ages from the coastal Alexander Archipelago (this study;  
Lesnek et al., 2018) do not consistently pre-date, match, or post-date exposure ages from  
adjacent boulders, we refrain from including bedrock-based  $^{10}\text{Be}$  ages in our mean age  
calculations (Figs. 9; 10). This negates biases when choosing which bedrock ages “match”  
370 nearby erratic ages and allows us to eliminate any concern over inheritance or post-ice retreat  
cover of these bedrock surfaces. While bedrock ages, especially when paired with boulder ages,  
are useful for identifying spatially variable subglacial erosion processes and issues with past  
cover and inheritance, they do not provide reliable age constraints on the timing of deglaciation.  
In light of this, we also recalculate relevant mean ages from Lesnek et al. (2018; 2020) using  
375 solely boulder  $^{10}\text{Be}$  ages to update these other regional chronologies.

## 5.2 $^{10}\text{Be}$ chronology incompatible with mapped Cordilleran Ice Sheet extent

We targeted areas of the northern Alexander Archipelago mapped as ice-free by previous studies to determine whether these areas were ILGM refugia. The most recent coastal CIS  
380 reconstructions show significant portions of the northern Alexander Archipelago as remaining ice-free throughout the ILGM (Fig. 2), with ice terminating close to the present shoreline – not on the continental shelf (Dalton et al., 2020; Lesnek et al., 2020). Our data, however, indicate that at least some of these areas that were mapped as refugia (southwestern Baranof and Kruzof islands) were covered by ice, and deglaciated around 15.4 – 14.8 ka. Our new evidence thus  
385 suggests that ice extended onto the continental shelf during the ILGM, as in the southern Alexander Archipelago (Lesnek et al., 2018). These discrepancies between previously mapped ice extents and those implied by our new exposure ages highlight the need to develop deglaciation chronologies elsewhere along the CIS coastal margin to provide updated mapping around the north Pacific.

390

## 5.3 Cordilleran Ice Sheet retreat across the Alexander Archipelago

Mean boulder  $^{10}\text{Be}$  exposure ages from Sumez Island in this study and Lesnek et al. (2018),  $16.0 \pm 1.2$  ka ( $n = 3$  boulders; 1 SD) and  $16.6 \pm 0.8$  ka ( $n = 3$  boulders; 1 SD), overlap  
395 within 1 standard deviation (Figs. 6; 9). However, three of the boulder  $^{36}\text{Cl}$  ages from southwestern Sumez Island do not overlap with the  $^{10}\text{Be}$  ages, at 1 standard deviation (Figs. 6; 9). We attribute this scatter to post-depositional surface erosion of the boulders. Surface erosion of rocks with low concentrations of native Cl (supplementary table S2), where the primary  $^{36}\text{Cl}$  production pathway is Ca-spallation (Marrero et al., 2016b), results in exposure ages that are

400 erroneously young. Thus, we interpret the oldest  $^{36}\text{Cl}$  exposure age ( $16.6 \pm 0.5$  ka; 19SEAK-02) as the closest constraint on deglaciation at that site. This  $^{36}\text{Cl}$  age overlaps with the  $^{10}\text{Be}$  ages from elsewhere on Suemez Island; we combine them and calculate a new, boulder-based mean deglaciation age of  $16.3 \pm 0.8$  ka ( $n = 10$  boulders; 1 SD) for Suemez Island.

We group together three of our sampling locations in the northern Alexander Archipelago  
405 that are ocean-facing: Kruzof, Biorka, and southern Baranof islands. As the CIS retreated from the continental shelf inland, these were the first areas presently above sea level to become ice-free. We calculate a mean  $^{10}\text{Be}$  boulder age of  $15.1 \pm 0.9$  ka ( $n = 12$  boulders; 1 SD) for the coastal northern Alexander Archipelago.

There are limited data from elsewhere in the northern Alexander Archipelago that  
410 constrain the timing of deglaciation. A basal pollen concentrate-based radiocarbon age from Hummingbird Lake (Fig. 7), southwestern Baranof Island dates to  $15.0 \pm 0.2$  ka, in agreement with the  $^{10}\text{Be}$  ages presented here and that collectively indicate coastal Baranof Island was deglaciated prior to this (Ager, 2019). Additionally, tephra layers from Mt. Edgumbe on Kruzof Island are dated to 13.1 ka (Riehle et al., 1992; Beget et al., 1998), and blanket many of  
415 the surrounding islands, suggesting that these areas were ice-free by then.

All three sample sites on Chichagof Island (Sites A – C) are not ocean-adjacent and characterized by a general lack of boulders. The boulders present were much smaller, and notably, shorter ( $< 0.5$  m high) than boulders sampled elsewhere across the Alexander Archipelago – we chose to sample these despite their size to provide minimum ages for  
420 deglaciation and to compare with available radio carbon constraints. They date between  $9.0 \pm 0.6$  and  $12.7 \pm 0.7$  ka. Their ages are younger than other age constraints for deglaciation on Chichagof Island; radiocarbon ages on shells from raised marine terraces on Chichagof Island

date back to  $14.2 \pm 0.6$  cal ka suggesting that the island was ice-free by this time (Baichtal et al.,  
in press). Smaller boulders are more susceptible to cover (whether snow, vegetation, or  
425 sediment), and may thus yield anomalously young  $^{10}\text{Be}$  ages. While a lack of large boulders  
found on Chichagof Island make it difficult to ascertain the timing of deglaciation, regional  
glacial and sea level history suggests Chichagof Island was deglaciated between 15.1 (when the  
coastal area deglaciated) and 14.2 ka (the age of shells in raised marine deposits). Therefore, our  
boulders likely have anomalously young exposure ages.

430 Our mean  $^{10}\text{Be}$  age from all sites along the coastal portion of the northern Alexander  
Archipelago of  $15.1 \pm 0.9$  ka ( $n = 12$  boulders; 1 SD) fits with the few other regional deglaciation  
constraints (Fig. 2) and overlaps within one standard deviation with the mean boulder exposure  
age from the southern Alexander Archipelago of  $16.3 \pm 0.8$  ka ( $n = 13$  boulders; 1  $\sigma$ ; this study;  
Lesnek et al., 2018; Lesnek et al., 2020).

435 While mean ages from the northern and southern Alexander Archipelago overlap within  
one standard deviation, it is possible that these areas deglaciated at slightly different times as  
these various sampling sites happened to become ice-free. Furthermore, local ice caps formed  
and radiated from massifs on Chichagof, Baranof, and Prince of Wales islands during the ILGM  
(Capps, 1932; Mann and Hamilton, 1995; Lesnek et al., 2020). These local ice caps served as a  
440 local ice source for the Alexander Archipelago and their locations and flow patterns may have  
led to some parts of the archipelago becoming ice-free before others. Thus, we present a range of  
deglaciation across the coastal Alexander Archipelago from between  $16.3 \pm 0.8$  ka and  $15.1 \pm$   
 $0.9$  ka

Ice retreat across the Alexander Archipelago is also registered in marine sediments off  
445 the former coastal CIS margin. Several marine sedimentary records (cores EW0408-26JC,

EW0408-66JC, EW0408-85JC) extending back to ~18.5 cal ka show the presence of IRD beginning ~18.5 ka, peaking at 17.5 – 16.5 ka and ceasing at 14.8 ka, reflecting a final retreat of marine-terminating ice (Praetorius and Mix, 2014). Furthermore, these IRD data record fluctuating but relatively elevated calving spanning 18.5 to 14.8 ka, perhaps indicating steady  
450 retreat punctuated by periods of accelerated melting.

Tephra from Mt. Edgecumbe (Kruzof Island) found in core EW0408-26JC is interpreted as being deposited in a submarine environment, suggesting that this core site was ice-free by 14.6 ka (Praetorius et al., 2016). Records of a subsequent eruption dated to ~13.1 cal ka from marine sediments in Sitka Sound (core EW0408-40JC) indicate that this area (between Baranof  
455 and Kruzof islands) must have been ice-free by this time (Addison et al., 2010). Finally, <sup>14</sup>C ages from mollusks found in a diamicton layer along the Gastineau Channel date to ~13.8 cal ka, reflecting the beginning of deglaciation near the mainland (Miller, 1973; we calibrate all uncalibrated <sup>14</sup>C ages with CALIB 8.2; Stuiver et al., 2021).

#### 460 **5.4 Chronologies of Cordilleran Ice Sheet deglaciation across the North Pacific**

Radiocarbon ages from the CIS margin reflect ice advance from ~20 – 17 ka, near the end of the gLGM at 19 ka. Dates from mammalian fossils in Shuká Káa on Prince of Wales Island indicate CIS advance ~20 ka in the Alexander Archipelago (Lesnek et al., 2018). Directly south of the  
465 Alexander Archipelago, on eastern Graham Island (Haida Gwaii) initial ice advance is dated to 24.1 – 22.5 cal ka with a <sup>14</sup>C date from a twig underlying glacial till (Blaise et al., 1990; Mathewes and Clague, 2017). Along the southwestern CIS margin, ice reached its maximum extent until ~18.3 ka in the Coquitlam Valley and ~17.0 ka in the Puget Sound area (Clague et al., 1980; Porter and Swanson, 1998).

470 Glacier chronologies from the northeastern Pacific coastline also reflect post-gLGM  
retreat. On Sanak Island, tephra near the bottom of a lake sediment core dates deglaciation before  
~15.9 ka, prior to the onset of CIS withdrawal in the Alexander Archipelago (Misarti et al.,  
2012). On Kodiak Island, final ILGM retreat dates to ~15.7 cal ka, as marked by a  $^{14}\text{C}$  age above  
glacio-tectonically altered sediments (Mann and Peteet, 1994). Directly north of the Alexander  
475 Archipelago, a  $^{14}\text{C}$  age from a log found within the Finger Glacier lateral moraine provides a  
minimum constraint on deglaciation at ~14.6 cal ka (Mann, 1986). Radiocarbon ages from a  
marine sediment core in Dixon Entrance date maximum CIS extent to before ~16.1 cal ka and  
retreat beginning before ~15.3 cal ka (Barrie and Conway, 1999). A marine sediment record  
from Vancouver Sound similarly dates maximum ice extent to 18.5 ka and retreat of the CIS  
480 onto the mainland by 16.4 ka (Blaise et al., 1990). Quaternary sediments on eastern Graham  
Island indicate the CIS was retreating by 17.8 cal ka (Blaise et al., 1990). Notably,  $^{10}\text{Be}$  ages on  
Calvert Island suggest ice retreated off the continental shelf at ~18 ka, pre-dating ice withdrawal  
onto land in the Alexander Archipelago (Darvill et al., 2018).

Marine sediment cores are interpreted to show ice retreat across the coastal northeastern  
485 Pacific. A marine sediment core (SO202-27-6) from the Gulf of Alaska captures a decrease in  
sea surface salinity ~16 ka, interpreted to reflect increased meltwater from the CIS margin  
(Maier et al., 2018). Another marine sediment core (EW0408-85JC) from off the coast of  
southern Alaska records a decrease in glacial-margin sediment accumulation at 16.9 ka as ice  
stagnated or began to retreat. (Davies et al., 2011). Reductions in salinity captured by planktonic  
490  $\delta^{18}\text{O}$  in this core at ~16.7 ka are interpreted as an increase in meltwater input from retreating  
glaciers. A transition from ice-proximal to laminated hemipelagic sediments at ~14.8 ka marks  
glacier retreat off the continental shelf and onto land. Additionally, a marine sediment core from

off Vancouver Island (MD02-2496) captures IRD deposition between ~17.0 and ~16.2 cal ka –  
indicating rapid regional deglaciation – and a minor IRD event at ~14.7 cal ka (Cosma et al.,  
495 2008).

Our new data showing ice retreat at  $15.1 \pm 0.9$  ka from the northern Alexander  
Archipelago, along with ages of deglaciation from the southern Alexander Archipelago ( $16.3 \pm$   
 $0.8$  ka; this study; Lesnek et al., 2018), are broadly synchronous with previously published ice  
retreat chronologies for the marine-terminating CIS margin elsewhere along the northeast Pacific  
500 Coast. However, while our chronology only documents deglaciation, it provides further evidence  
of a delayed ILGM across the coastal CIS compared to the gLGM maximum extents of alpine  
glaciers in mainland Alaska (Briner et al., 2017), parts of southern Alaska (Reger et al., 1996),  
and the LIS (Dalton et al., 2020).

## 505 5.5 Paleoclimate Records from the North Pacific

Several paleoclimate records from around the North Pacific span our interval of CIS deglaciation  
in the Alexander Archipelago. A combined diatom assemblage- and alkenone-derived record of  
sea surface temperatures (SSTs) from the Bering Sea (Core 51JPC), records perennial sea ice  
510 from ~22.5 ka (beginning of record) to 17 ka, and increased SSTs beginning ~16.9 ka before a  
notable shift back to annual sea ice ~16.7 ka (Caissie et al., 2010). In the northern Gulf of Alaska  
(Core EW0408-85JC),  $\delta^{18}\text{O}$  data document increasing SSTs at 16.7 ka and again at ~14.7 ka  
(Davies et al., 2011). Alkenone-inferred paleo-SST reconstructions from this same core show the  
lowest SSTs (~5°C) circa 17.0 ka, with increased SSTs beginning ~16.5 ka, and a rapid ~3-4 °C  
515 rise in SSTs from 15.2 to 14.7 ka (Praetorius et al., 2015). Alkenone-inferred SST and  $\delta^{18}\text{O}$   
records from the Gulf of Alaska also record increased SSTs of ~3°C at 14.7 ka (cores EW0408-

26JC, EW0408-66JC; Praetorius et al., 2016). Off Vancouver Island, Mg/Ca temperature reconstructions from subsurface-dwelling *N. pachyderma* indicate two stages of warming of 2°C at 17.2 – 16 ka, and 15.5 – 14.0 ka, while surface-dwelling *G. bulloides* record a 3°C SST increase from 15.0 – 14.0 ka (core MD02-2496; Taylor et al., 2014), all within uncertainty of coastal Alexander Archipelago ice retreat. Alkenone SST reconstructions from another nearby core (core JT96-09) also indicates a 4°C increase in SST at ~14.7 ka (Kienast and McKay, 2001).

There are few terrestrial paleoclimate data that span the last deglacial period from SE AK and coastal British Columbia. Cordilleran ice cover until ~15 ka across much of the region impeded the preservation of many terrestrial records – however, there are limited ice core, speleothem, and lake records that date back to early regional deglaciation or prior. Fisher et al. (2008) developed an ice core record from Mt. Logan, British Columbia. However, measurements of  $\delta^{18}\text{O}$  likely represent shifting precipitation sources, rather than paleoclimate changes. A growth hiatus in a speleothem from El Capitan Cave (southern Alexander Archipelago) spanning ~41.5 to ~13.4 ka suggests the cave was either overridden by the CIS, experienced permafrost conditions and a mean annual air temperature  $< 0^\circ\text{C}$ , or lacked drip water (Wilcox et al., 2019). However, El Capitan Cave is ~60 km inland of the outermost coastal region and therefore may have still experienced these conditions while the outer coast deglaciated. At Hummingbird Lake, southwestern Baranof Island, pollen records indicate *Pinus contorta* dominated from ~15.2 ka to 14 ka, which is interpreted to represent *Pinus contorta* response to the beginnings of Gulf of Alaska ocean warming at ~16.5 ka (Praetorius et al., 2015; Ager, 2019). This record suggests increased air temperatures around deglaciation of the Alexander Archipelago between  $16.3 \pm 0.8$  ka and  $15.1 \pm 0.9$  ka

## 540 **5.6 Implications for early human migration**

Several studies have focused on scrutinizing potential areas of ILGM glacial refugia in the Alexander Archipelago through a human migration perspective (Carrara et al., 2007; Lesnek et al., 2018), building off similar approaches from elsewhere in the North Pacific (e.g., Warner et al., 1982; Mann and Peteet, 1994; Misarti et al., 2012). Our study focused on southern Baranof  
545 and Kruzof islands because previous mapping suggested that parts of these areas were ice-free throughout the ILGM (Carrara et al., 2003; Carrara et al., 2007). However, our  $^{10}\text{Be}$  ages from southern Baranof Island indicate these areas were glaciated throughout the ILGM and not available for human habitation between  $\sim 20$  ka and  $\sim 15.4$  ka. Our exposure ages from Kruzof  
550 Island also suggest that this area was not ice free until  $\sim 14.8$  ka.

These results indicate that some of the last major unevaluated areas of possible refugia that are presently above sea-level were covered by ice during the ILGM. At its maximum extent, ice likely extended onto the then-exposed continental shelf. Ice occupation of the continental shelf – or at least parts of the shelf – off the Alexander Archipelago was relatively brief, from  
555  $\sim 20.0$  to  $\sim 16.0$  ka (Lesnek et al., 2018). Lowered global sea levels indicate the shelf would have been above contemporary sea level during this time and until  $\sim 11 - 8$  ka, when sea level neared modern levels in the Alexander Archipelago (Baichtal et al., in press). At a minimum, ice lobes would have existed within the major shelf troughs (e.g., Chatham Strait), likely crossing the entire shelf at these locations; at a maximum, the whole continental shelf may have been  
560 occupied by ice from  $\sim 20$  to  $\sim 16$  ka. Whether portions of the shelf remained ice-free during the ILGM is unknown, but it is possible. Based on the immediate colonization of *Pinus* at 15.2 ka in Hummingbird Lake, and as early as  $\sim 15.4$  ka on Pleasant Island, there were likely ice-free areas on the shelf throughout the ILGM (Hansen and Engstrom, 1996; Ager, 2019).

## 6 Conclusions

565

We conclude that several areas in SE AK previously mapped as ice-free through the ILGM were covered by ice until between ~16.3 and ~15.1 ka.  $^{10}\text{Be}$  ages from boulders suggest that the northern coastal Alexander Archipelago deglaciated at  $15.1 \pm 0.9$  ka, while  $^{10}\text{Be}$  and  $^{36}\text{Cl}$  ages date ice retreat in the southern portion at  $16.3 \pm 0.8$  ka, following a ILGM that begin after ~20 ka

570

(Lesnek et al., 2018; Lesnek et al., 2020) The timing of deglaciation in the Alexander Archipelago is similar to some other sites around the CIS coastal margin (e.g., Mann and Peteet, 1994; Misarti et al., 2012), but later than other locations (e.g., Darvill et al., 2018). Notably, the deglaciation in SE AK is later than in mainland Alaska and Kodiak and Sanak Islands, Alaska, where records are more aligned with the gLGM. The timing of deglaciation in the Alexander

575

Archipelago is broadly synchronous with regional records of local ocean and air temperature increases. We also found that anomalously old  $^{10}\text{Be}$  ages of bedrock surfaces are due to inheritance caused by insufficient ice sheet erosion, and thus, we caution using ages from bedrock surfaces as direct constraints on ice retreat without additional boulder ages along the coastal margins of the CIS.

580

Our data indicate that previous mapping of the coastal CIS can be spatially and temporally improved. We suggest that ice likely extended out on the continental shelf along the Alexander Archipelago. We are increasingly confident that areas of the coastal CIS mapped as ice-free throughout the ILGM were in fact covered by ice, and that refugia, if any, would have been located on the exposed continental shelf. Although more logistically challenging,

585

subsequent studies should evaluate the existence of ILGM refugia in the Alexander Archipelago by focusing on the previously exposed continental shelf. Special attention should be given to the northern Alexander Archipelago where ice masses were fed by local ice caps and thus may not

have been as extensive, as opposed to elsewhere in the northeastern Pacific where ice was sourced from the main body of the CIS.

590

825 **Figures**

830 Figure 1: Map of the north Pacific region showing ice limits at 18.0 ka from Dalton et al. (2020)  
by the red box. Orange dots indicate locations of marine sediment cores: 51-JPC (Caissie et al.,  
2010), SO202-27-6 (Maier et al., 2018), EW0408-85JC (Davies et al., 2011; Praetorius and Mix,  
2014, Praetorius et al., 2015), EW0408-66JC (Praetorius and Mix, 2014; Praetorius et al., 2016),  
EW0408-26JC (Praetorius and Mix, 2014; Praetorius et al., 2016), EW0408-40JC (Addison et  
al., 2010), MD02-2496 (Cosma and Hendy, 2008), and JT96-09 (Kienast and McKay, 2001).  
835 Blue dots indicate location of terrestrial study sites: Sanak Island (Misarti et al., 2012), Kodiak  
Island (Mann and Peteet, 1994), Mt. Logan (Fisher et al., 2008), Finger Glacier (Mann 1986),  
Haida Gwaii (Clague et al., 1982; Mathewes and Clague, 1982), Calvert Island, (Darvill et al.,  
2018), Coquitlam Valley (Clague et al., 1980), and Puget Sound (Porter and Swanson, 1998).

840 Figure 2: The Alexander Archipelago showing relevant marine sediment cores and terrestrial  
chronologies. Shaded white areas show hypothesized ILGM CIS extent (Lesnek et al., 2020). -  
160 m relative sea level lowering after Baichtal et al. (in press). Red boxes and points show  
sampling locations from this study. Blue box shows extent of study area from Lesnek et al.  
(2018; 2020). Orange dots represent locations of marine sediment cores: EW0408-66JC and  
845 EW0408-26J (Praetorius and Mix, 2014; Praetorius et al., 2016) and EW0408-40JC (Addison et  
al., 2010). Blue dots indicate locations of relevant terrestrial study sites: Gastineau Channel  
(Miller, 1973), Pleasant Island (Hansen and Engstrom, 1996), Hummingbird Lake (Ager, 2019),  
Shuká Káa (Lesnek et al., 2018), and El Capitan Cave (Wilcox et al., 2019).

850 Figure 3: Sample photos from 2019 field season. All  $^{10}\text{Be}$  ages shown with  $1 \sigma$  internal uncertainty. Note the grooves and chatter marks on bedrock of 19SEAK-18.

Figure 4: Sample photos from 2018 and 2020 field season. All  $^{10}\text{Be}$  ages are shown with  $1 \sigma$  internal uncertainty. Note the relatively small size of 20SEAK-15.

855

Figure 5: Basalt samples and  $^{36}\text{Cl}$  ages from southwestern Suemez Island. Ages are reported at 1  $\sigma$  internal uncertainty.

<sup>a</sup> Elevations and positions were recorded with a Garmin handheld GPS receiver (~5 m vertical uncertainty) or GAIA GPS (~5 m vertical uncertainty) or AMIS results from PRIME Lab are standardized to 07KNSD (Nishizumi et al., 2007); ratios are blank corrected and shown at 1 SD uncertainty.  
<sup>b</sup> <sup>10</sup>Be ages reported with at one σ internal uncertainties and calculated with CRONUS-Earth calculator v. 3 (Balco et al., 2008) using the Arctic production rate (Young et al., 2013) or global production rate (Borchers et al., 2016) and Ln scaling.

Table 2: <sup>36</sup>Cl surface exposure age data

Sample ID	Sample type	Latitude (°N)	Longitude (°W)	Elevation (m.a.s.l.) Figure 6:  $^{10}\text{Be}$  and  $^{36}\text{Cl}$  ages from samples collected on Suemez on island: red dot marks sampling site from this study, blue dot marks sampling site from Lesnek et al., 2018). All  $^{10}\text{Be}$  and  $^{36}\text{Cl}$  ages reported with  $1 \sigma$  internal uncertainty.

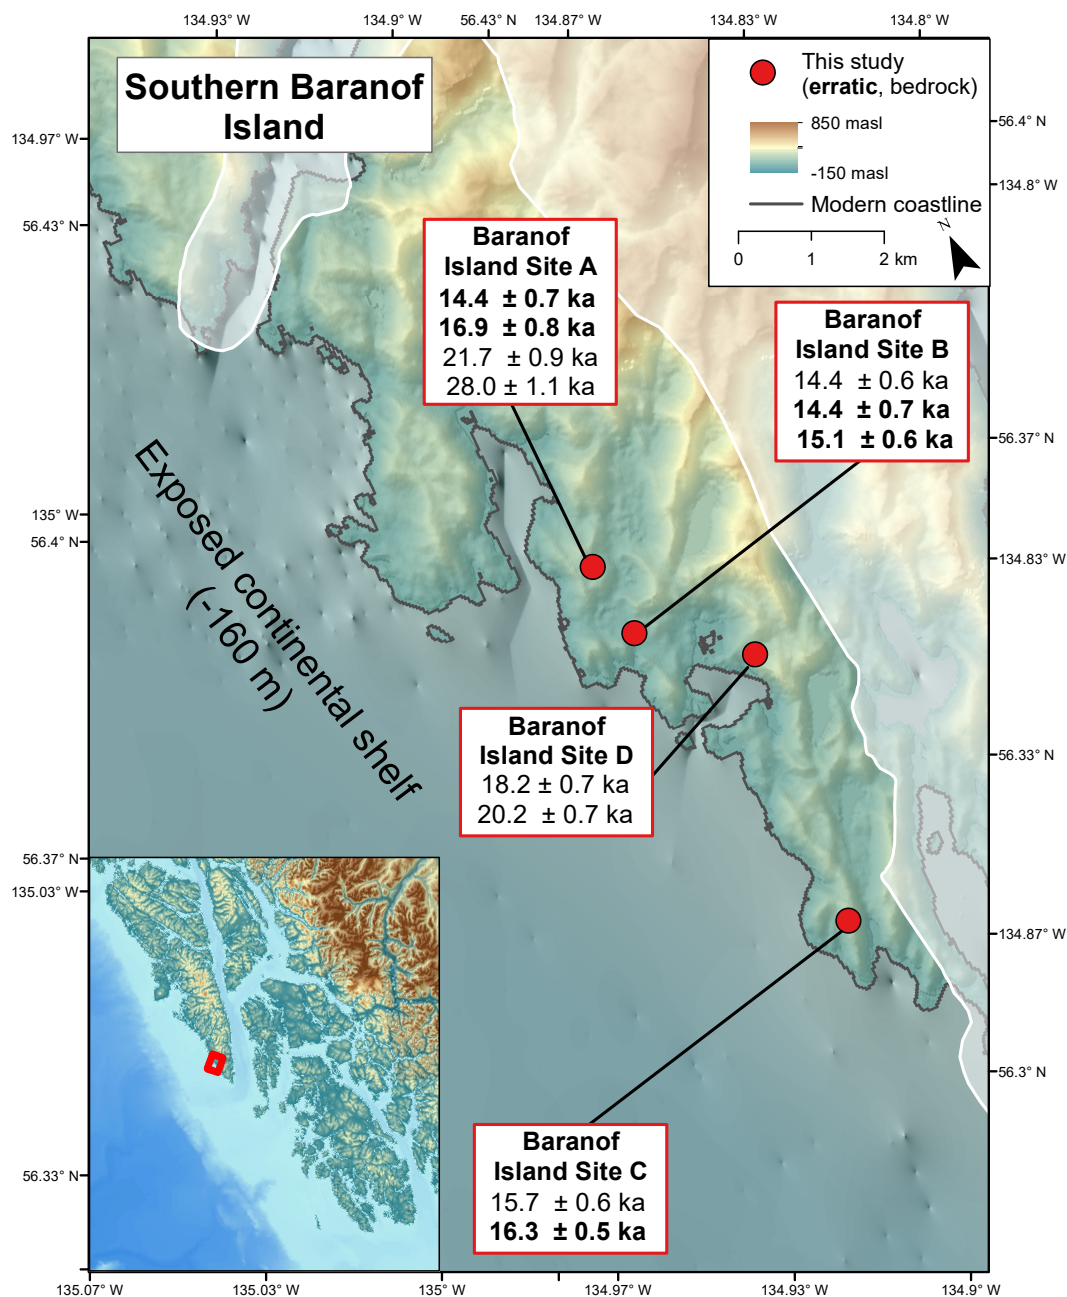

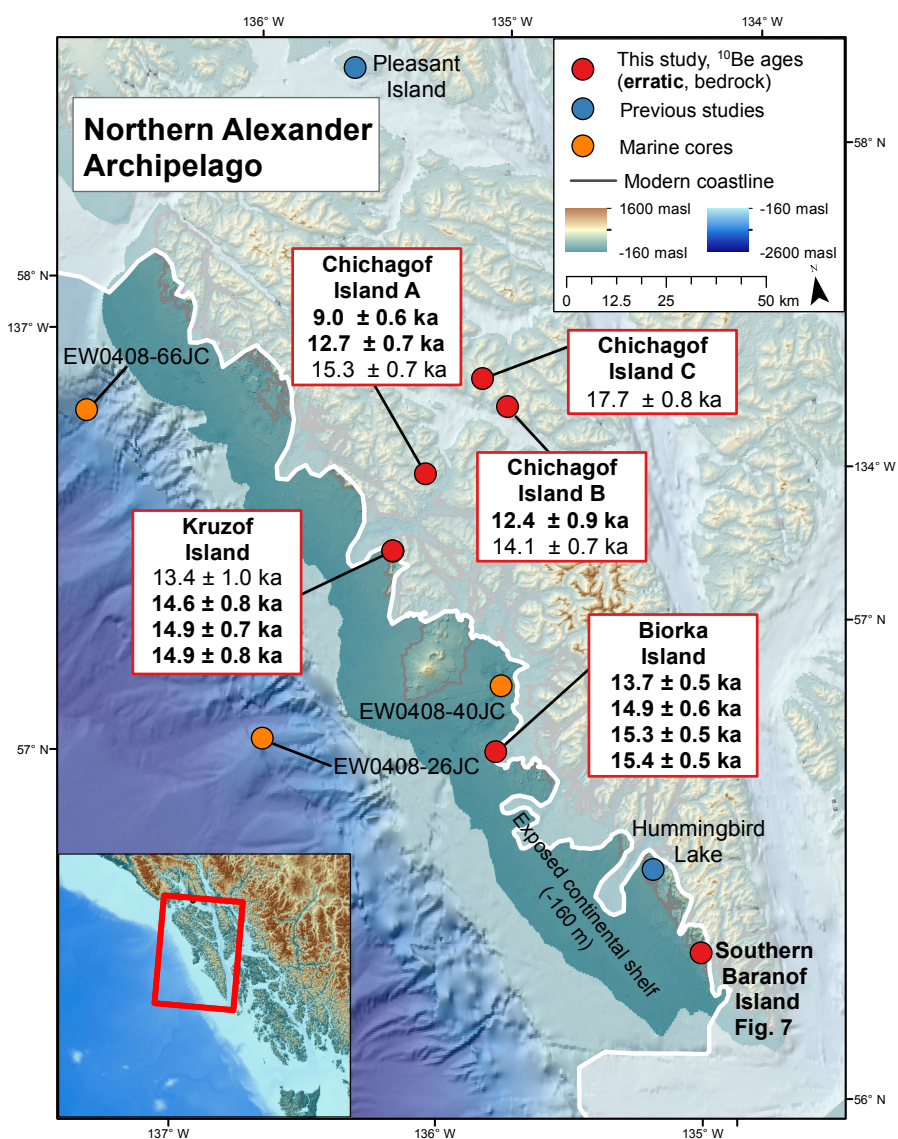

Figure 7:  $^{10}\text{Be}$  ages from sampling sites on southern Baranof Island. All ages are reported with 1  $\sigma$  internal error. CIS ILGM extent after Carrara et al. (2007).

885 Figure 8:  $^{10}\text{Be}$  ages from sampling sites in the northern Alexander Archipelago. All ages are reported with  $1\sigma$  internal error. ILGM CIS extent after Lesnek et al. (2020). Exposed continental shelf at -160 m below modern sea level Baichtal et al. (in press). Yellow dots show location of relevant marine sediment cores: EW0408-66JC and EW0408-26JC (Praetorius and Mix, 2014; Praetorius et al., 2016) and EW0408-40JC (Addison et al., 2010). Blue dots show locations of relevant terrestrial study sites: Pleasant Island (Hansen and Engstrom, 1996) and Hummingbird Lake (Ager, 2019).  
890

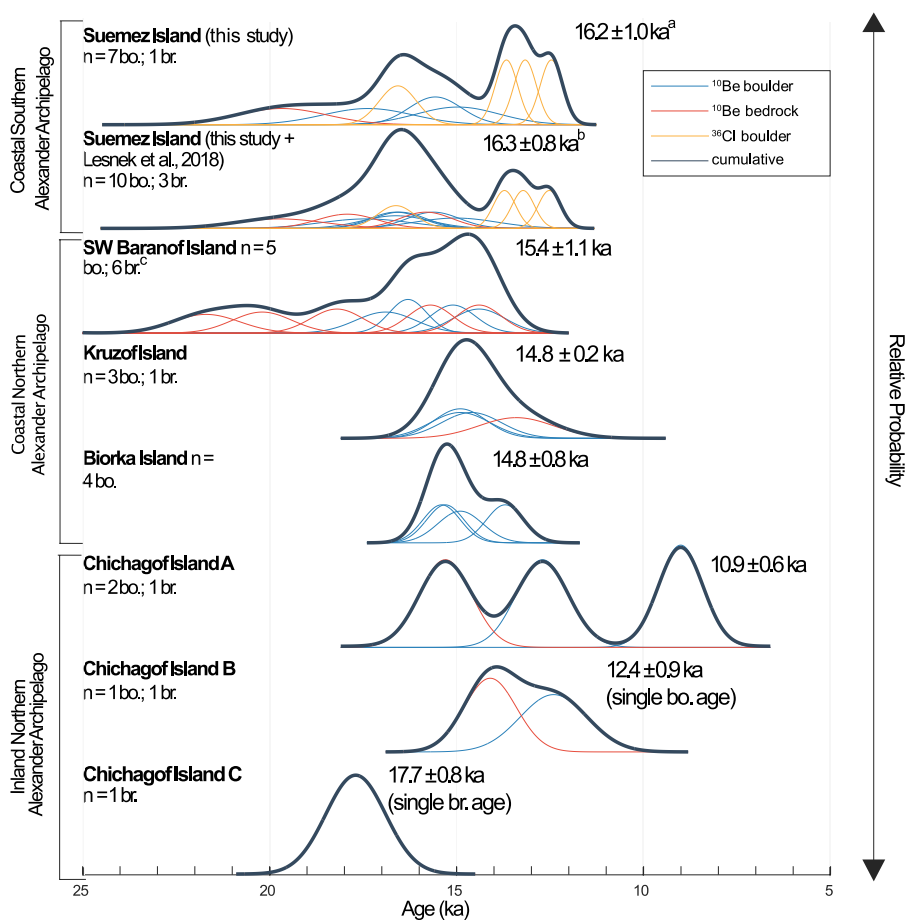

Figure 9: Relative probably plots of bedrock (red) and boulder (blue)  $^{10}\text{Be}$  and  $^{36}\text{Cl}$  boulder (yellow) ages from this study calculated with  $1\sigma$  internal uncertainty. bo. = boulder, br. = bedrock. All ages shown are mean ages from only boulders at each sample site reported with 1 SD unless noted. <sup>a</sup>Average of all  $^{10}\text{Be}$  boulder ages and oldest  $^{36}\text{Cl}$  boulder age with 1 SD. <sup>b</sup>Average of all  $^{10}\text{Be}$  boulder ages (this study and Lesnek et al., 2018) and oldest  $^{36}\text{Cl}$  boulder age (this study). <sup>c</sup>One old outlier at  $28.0 \pm 1.1$  ka not shown.

Figure 10: A) Proxy Northern Hemisphere temperature anomaly relative to early Holocene with 1  $\sigma$  error (Shakun et al., 2012). B) Eustatic sea-level curve (Spratt and Lisiecki, 2016). C) Gulf of Alaska surface salinity  $\delta^{18}\text{O}$  record (Core SO202-27-6; Maier et al., 2018). D)  $U^k_{37}$  temperature reconstruction from off the coast of the Alexander Archipelago (Cores EW0408-26JC, EW0408-66JC; Praetorius et al., 2016). E) Ice rafted debris record from off Vancouver Island (Core MD02-2496; Cosma et al., 2008). F) – G) Relative probability plots of boulder  $^{10}\text{Be}$  ages from the coastal Alexander Archipelago, with mean boulder ages and 1  $\sigma$  reported (this study; Lesnek et al., 2018; 2020).
