## Abstract

A new luminescence erosion-meter has huge potential for inferring erosion rates on sub-millennial scales for both steady and transient states of erosion, which is not currently ~~not~~-possible with any existing techniques capable of measuring erosion. This study applies new rock luminescence techniques to a well-constrained scenario provided by the Beinn Alligin rock avalanche, NW Scotland. Boulders in this deposit are lithologically consistent, have known cosmogenic nuclide ages, and independently-derived Holocene erosion rates. We find that luminescence-derived exposure ages for the Beinn Alligin rock avalanche were an order of magnitude younger than existing cosmogenic nuclide exposure ages, suggestive of high erosion rates (as supported by field evidence of quartz grain protrusions on the rock surfaces). Erosion rates determined by luminescence were consistent with independently-derived rates measured from boulder-edge roundness. Inversion modelling indicates a transient state of erosion reflecting the stochastic nature of erosional processes over the last ~4.5 ka in the wet, temperate climate of NW Scotland. Erosion was likely modulated by known fluctuations in moisture availability, and to a lesser extent temperature, which controlled the extent of chemical weathering of these highly-lithified rocks prior to erosion. The use of a multi-elevated temperature, post-infra-red, infra-red stimulated luminescence (MET-pIRIR) protocol (50, 150 and 225°C) was advantageous as it identified samples with complexities that would not have been observed using only the standard IRSL signal measured at 50 °C, such as that introduced by within-sample variability (e.g. surficial coatings). This study demonstrates that the luminescence erosion-meter can infer accurate erosion rates on sub-millennial scales and identify transient states of erosion (i.e. stochastic processes) in agreement with independently-derived erosion rates for the same deposit.

## 1. Introduction

30 Rock erosion is dependent upon a variety of internal (e.g. mineralogy, grain size, porosity, structures) and external (e.g.  
31 temperature, moisture availability, snow cover, wind, aspect) factors. Chemical and/or physical weathering of rocks (or rock  
32 decay; Hall et al. 2012) breaks down the surficial materials making them available for transportation (i.e. erosion), where the  
33 rates and processes of degradation is primarily controlled by the rock lithology (e.g. Twidale, 1982; Ford and Williams,  
34 1989). For boulders with similar lithologies, the erosion rate is conditioned by weathering principally caused by moisture  
35 availability, but also temperature, and in some cases biological factors (Hall et al. 2012). It is widely reported that warmer  
36 temperatures increase most rates of chemical activity, while sub-zero temperatures arrest chemical activity on a seasonal  
37 basis. However, cold temperatures alone do not preclude chemical weathering (Thorn et al. 2001). As such, rock erosion  
38 rates will be sensitive to changing climate (moisture availability, temperature) such as that experienced throughout the Late  
39 Holocene (i.e. last 4 ka) (e.g. Charman, 2010), in addition to that forecast for the future due to anthropogenic climate change  
40 (e.g. Stocker et al. 2013).

41 Measuring erosion rates over shorter ( $\leq 10^3$  a) and longer ( $\geq 10^4$  a) integration times is advantageous as each targets a different  
42 phenomenon of erosion. Longer timeframes will inform on how landscapes respond to changing large-scale climatic and  
43 tectonic conditions (e.g. Herman et al. 2010), whereas shorter timeframes assess local or regional responses to shorter-lived  
44 environmental conditions (e.g. climate fluctuations). A number of techniques can constrain long-term, landscape erosion  
45 rates on  $\geq 10^4$  a timeframes, such as cosmogenic nuclides (e.g. Lal, 1991; Braun et al. 2006; Balco et al. 2008) or  
46 thermochronology (Reiners and Brandon, 2006). While observational measurements on very short timeframes  $\leq 10^2$  a are  
47 performed with both direct contact (e.g. Hanna, 1966; High and Hanna, 1970; Trudgill et al. 1989) and non-contact (e.g.  
48 Swantesson, 1989; Swantesson et al. 2006) techniques. However, until now it has been difficult to constrain erosion rates on  
49  $10^2$  to  $10^3$  a timeframes due to a lack of techniques with the required sensitivity and resolution.

50 The luminescence signal within mineral grains (quartz and feldspar) is reset when a rock surface is exposed to  
51 sunlight for the first time (e.g. Habermann et al. 2000; Polikreti et al. 2002; Vafiadou et al. 2007). With continued exposure  
52 the luminescence signal resetting in the mineral grains propagates to increasing depths (i.e. the luminescence depth profile is  
53 a function of time). Improved understanding of this fundamental principle has led to the development of new applications of  
54 luminescence; constraining the timing of rock exposure events (Laskaris and Liritzis, 2011; Sohbaty et al. 2011; Lehmann et  
55 al. 2018) and rock surface erosion rates (Sohbaty et al. 2018; Lehmann et al. 2019a,b). Brown (2020) even combine these  
56 phenomena within model simulations to explore different sample histories of exposure and burial, to inform  
57 geomorphological interpretations of luminescence depth profiles measured for samples collected from the natural  
58 environment. Here, we measure-investigate erosion rates, rather than weathering rates as the luminescence technique  
59 specifically measures the light penetration into a rock surface after the removal of material (i.e. erosion), occurring after the  
60 in-situ rock breakdown (i.e. weathering). Luminescence depth profiles are a product of the competing effects of time (which  
61 allows the bleaching front to propagate to greater depths) and erosion (which exhumes the bleaching front closer to the  
62 surface). Existing studies have suggested that rock luminescence exposure dating is only feasible for very short timeframes

63 (e.g. <300 a; Sohbati et al. 2018) as light penetrates faster than the material can be removed, and/or in settings where erosion  
64 rates are <1 mm/ka (Lehmann et al. 2018). Beyond this, the dominant control on the luminescence depth profile is erosion,  
65 rather than time, hence if time can be parameterised, then erosion can be determined (and vice versa). Recent findings from  
66 erosion simulations compared with measured data have shown that the erosion rates derived from luminescence depth  
67 profiles can be accurate even where stochastic erosion was experienced in nature (Brown and Moon, 2019).

68 New luminescence techniques have the potential to derive  $10^2$  to  $10^3$  a scale erosion rates because of two important  
69 characteristics: (1) measurable luminescence depth profiles can develop in a rock surface over extremely short durations of  
70 sunlight exposure (e.g. days; Polikreti et al. 2003, or years; Lehmann et al. 2018); and (2) luminescence depth profiles are  
71 sensitive to mm-scale erosion. Conversely, cosmogenic nuclides are sensitive to m-scale erosion, depending on the density  
72 (e.g. Lal, 1991). Therefore, the new luminescence erosion-meter has the potential to provide a step-change in capabilities of  
73 measuring erosion rates on currently impossible  $10^2$  to  $10^3$  a timeframes. However, its application has been limited to few  
74 studies (e.g. Sohbati et al. 2018; Lehmann et al. 2019b) validated against long-term erosion rates of landscape evolution from  
75 global or regional datasets rather than local, independently-constrained erosion rates derived from the same rock type.

76 This study tests the accuracy and applicability of rock erosion rates inferred from luminescence techniques in a new  
77 latitudinal ( $57^\circ\text{N}$ ) and climate (wet, temperate) setting with independently-constrained erosion rates. The Beinn Alligin rock  
78 avalanche in NW Scotland (Fig. 1) provides a well-constrained test scenario as: (1) the boulders were sourced from a single  
79 fault-bounded failure scarp occurring within sandstones of the Torridonian group (i.e. rocks are likely to be lithologically  
80 consistent); (2) all boulder samples share an identical exposure history as they were deposited by a single, instantaneous  
81 event (Ballantyne and Stone, 2004); (3) independent cosmogenic exposure ages constrain the timing of the rock avalanche  
82 (Ballantyne and Stone, 2004); and (4) independently-derived erosion rates over the last ~4 ka for the boulders of the Beinn  
83 Alligin rock avalanche uniquely provide constraints on erosion rates (Kirkbride and Bell, 2010).

## 84 2. Theoretical background

85 The propagation of a bleaching front (i.e. the depth at which the luminescence signal has been reduced by 50 %) into a rock  
86 surface can be described by a double exponential function (Eq. 1), where  $L_x$  is the luminescence measured with depth ( $x$ )  
87 from the rock surface,  $L_0$  is the saturation limit for this sample (determined experimentally),  $t$  is the exposure time,  $\overline{\sigma\phi_0}$  is  
88 the intensity of light of a specific wavelength at the rock surface, and  $\mu$  is the light attenuation coefficient. To determine the  
89 exposure time ( $t$ ) of a rock surface (and also erosion rates), it is necessary to parameterise  $\mu$  and  $\overline{\sigma\phi_0}$ , which are likely  
90 unique to any specific rock lithology and natural sunlight conditions (e.g. latitude, cloudiness) of the sample being dated,  
91 respectively. Therefore, to provide accurate luminescence exposure ages (and also ~~er~~ erosion rates),  $\mu$  and  $\overline{\sigma\phi_0}$  must be  
92 calibrated using samples of known-age with the same lithology and natural sunlight conditions (e.g. a nearby road-cutting).

$$93 L_x = L_0 e^{-\overline{\sigma\phi_0} t e^{-\mu x}} \quad (1)$$

94 Studies have applied rock luminescence techniques (mostly exposure dating) to a variety of lithologies including granites,  
95 gneisses (Lehmann et al. 2018, 2019a,b; Meyer et al. 2019), sandstones (Sohbati et al. 2012; Chapot et al. 2012; Pederson et

96 al. 2014), ~~and~~ quartzites (Glignac et al. 2019) and carbonate limestone (Brill et al. 2021). These studies showed that  $\mu$  is  
97 highly dependent upon the rock lithology, where mineralogy has a strong control on the rock transparency. This is supported  
98 by direct measurements of  $\mu$  for a variety of lithologies (greywacke, sandstone, granite, and quartzite) using a spectrometer  
99 (Ou et al. 2018). In addition to mineralogy, it has also been shown that the precipitation of dark Fe-hydroxides (Meyer et al.  
100 2018) and rock varnishing (or weathering crusts) (e.g. Luo et al. 2019) can influence  $\mu$  by changing the rock transparency  
101 principally at the rock surface. Mineralogy is broadly a constant variable over time. However, the formation of precipitates  
102 or rock varnishing can be time-variable due to changing environmental factors external to the rock; thus, we ~~must~~should  
103 consider the possibility that  $\mu$  may be time-variable. Consequently, investigating the rock opacity of each sample is  
104 important to assess whether the known-age samples used to parameterise  $\mu$  and  $\overline{\sigma\phi_0}$  were consistent with the unknown-age  
105 samples used for exposure dating or erosion rates.

106 Since the introduction of the new rock luminescence techniques, most studies on K-feldspar (except Luo et al.  
107 2019) have only utilised the IR<sub>50</sub> signal as it bleaches more efficiently with depth into rock surfaces compared to higher  
108 temperature post-IR IRSL signals (e.g. Luo et al. 2019; Ou et al. 2018). However, electron multiplying charged coupled  
109 device (EMCCD) measurements of four rock types (quartzite, orthoclase and two different granites) have shown that the  
110 post-IR IRSL signals of rock slices were dominated by K-feldspars, while Na-rich feldspars can contribute towards the IR<sub>50</sub>  
111 signal (Thomsen et al. 2018). It is possible that the different IRSL signals will have different luminescence characteristics  
112 (e.g. bleaching rates, fading rates, saturation levels, light attenuation, internal mineral composition) that could be exploited  
113 during measurements. Luo et al. (2019) used the post-IR IRSL signals with a multiple elevated temperature (MET) protocol  
114 (50, 110, 170, 225 °C) to demonstrate that all the IRSL signals provide luminescence depth profiles, but the lower  
115 temperature signals penetrated further into the rock with depth. The authors fit the four IRSL signals to improve the accuracy  
116 of their parameterisation of  $\mu$  and  $\overline{\sigma\phi_0}$ . However, no study has yet used the MET-post IR IRSL protocol to exploit the  
117 differing luminescence characteristics of the ~~simultaneously~~successively-measured IRSL signals to provide an internal  
118 quality control check on the reliability of the measured data, i.e. the luminescence depth profile will penetrate deeper in to  
119 the rock for the IR<sub>50</sub> signal than the pIRIR<sub>150</sub> signal, which in turn will penetrate deeper than the pIRIR<sub>225</sub> signal. However,  
120 all three signals should determine the same erosion rates if the model parameterisation (i.e.  $\mu$  and  $\overline{\sigma\phi_0}$ ) is accurate. To  
121 maximise the potential information that could be derived from the samples, this study applied a MET-post IR IRSL protocol  
122 (50, 150 and 225 °C).

123 For determining erosion rates for rock surfaces of known exposure age, Sohbaty et al. (2018) used a confluent  
124 hypergeometric function to provide an analytical solution, but assuming only steady-state erosion. Lehmann et al. (2019a)  
125 provide a numerical approach that exploits the differential sensitivities to erosion of the luminescence (short-term) and  
126 cosmogenic nuclide (longer-term) techniques to erosion to infer erosion histories (steady state and transient over time) for  
127 rock surfaces. ~~By applying a step function from zero to increased constant erosion rates at certain times in history, This~~  
128 approach uses the experimental data from the luminescence depth profiles and the <sup>10</sup>Be concentrations for each sample.

129 Modelling of the luminescence depth profiles accounts for the electron trapping dependent upon the environmental dose-rate  
130 and  $D_0$  but does not consider athermal loss of the signal (i.e. anomalous fading) as it has been demonstrated to have a  
131 negligible impact upon the luminescence depth profiles (Lehmann et al. 2019a). Modelling of the  $^{10}\text{Be}$  concentrations  
132 assumes ~~that no inheritance of the cosmogenic nuclides from prior exposure has occurred,~~ and that the  $^{10}\text{Be}$  concentrations  
133 have been corrected for ~~the sample depth, sample and density and topographical shielding, local production rates, and the~~  
134 ~~sample location (longitude, latitude and elevation).~~ The luminescence depth profiles and ~~c~~The combined experimental data  
135 for the luminescence depth profiles and ~~C~~cosmogenic nuclide concentrations are solved simultaneously for two unknowns:  
136 the exposure ~~a~~duration and the erosion ~~r~~ate history as defined by a step function (e.g. zero erosion for an initial period of  
137 time followed by an instant increase to a constant erosion rate). Forward modelling is used to simply simulate a projected  
138 outcome and here it is used to calculate all of the possible ~~combinations of~~ luminescence depth profiles and  $^{10}\text{Be}$   
139 ~~concentrations~~ for these synthetic erosion and exposure histories. Inversion modelling matches measured data with the  
140 outcome of simulations to determine best fit of the raw data. Here, inversion modelling was used to validate the  
141 luminescence depth profile and cosmogenic nuclide concentration data against the synthetic erosion and exposure histories  
142 to determine the combinations with the highest likelihood. Throughout these modelling experiments, a forbidden zone is  
143 ~~determined~~defined where ~~the~~by range of possible solutions combinations of erosion rates and durations that are in excess of  
144 ~~those that are feasible~~not possible given for the experimental measured  $^{10}\text{Be}$  concentrations ~~provided for the sample; these~~  
145 solutions are excluded from the parameter ranges used for the inversion model. For example, the forbidden zone identified in  
146 the inversion model profile shown in Fig. 7A is restricted to ranges from ca.  $10^4$  mm/ka for durations of ca. 100 a to ca.  $10^3$   
147 mm/ka for ca. >3000 a.

148 The approach of Lehmann et al. (2019a) can model synthetic erosion histories in both steady and transient states.  
149 Steady state erosion ~~assumes~~ is defined as a constant erosion rate over a portion of ~~throughout~~ the ~~duration~~total duration of  
150 surface exposure. Transient erosion is typical of shorter exposure histories where a steady state of erosion has not yet been  
151 reached and the erosion rate varies over time. In the approach of Lehmann et al. (2019a), transient erosion is ~~and is~~ defined  
152 by erosion rates that decrease linearly with increased timing of erosion onset within the parameter space, ultimately reaching  
153 steady state (i.e. a constant erosion rate) ~~Transient erosion varies with time and was simulated here by assuming that the~~  
154 ~~evolution of erosion in time follows a stepped function of a fixed increase in erosion rate from zero for varying durations~~  
155 ~~throughout the exposure history for each synthetic erosion history simulated.~~ An illustration of this is provided by Fig. 7A  
156 where transient erosion rates of ca.  $10^4$  mm/ka were inferred for a minimum duration of ca.  $\leq 1$  a, and extending up to ca.  $10^3$   
157 mm/ka for durations up to ca. 50 a. Beyond ca. 50 a, a steady state of erosion was reached at a constant erosion rate of ca.  
158  $10^3$  mm/ka, represented by the flattening of the profile with the highest likelihood. Alternatively, a profile indicative of a  
159 transient state of erosion where no steady state has been established is illustrated by Fig. 7D where transient erosion rates of  
160 between ca.  $10^2$  mm/ka were inferred for a minimum duration of ca.  $\leq 1$  a, and extending up to ca.  $10^1$  mm/ka for durations  
161 beyond ca. 200 a. This numerical approach (Lehmann et al. 2019a) allows erosion history to be considered as non-constant

162 in time (i.e. transient), in addition to steady-state, and so it is more indicative of the stochastic erosional processes (driven by  
163 temperature, precipitation, snow cover, wind) in nature.

### 164 **3. The Beinn Alligin rock avalanche**

165 Today, average winter and summer temperatures in NW Scotland are 7°C and 18°C, respectively, while average annual  
166 precipitation (mostly rainfall) is high (ca. 2,300 mm/a) (Met Office, 2021). The Beinn Alligin rock avalanche (57°35'N,  
167 05°34'W) is a distinct, lobate deposit of large boulders that is 1.25 km long and covers an area of 0.38 km<sup>2</sup> (Fig. 1). It has  
168 previously been ascribed various origins including a rockslide onto a former corrie glacier (e.g. Ballantyne, 1987; Gordon,  
169 1993) and a former rock glacier (Sissons, 1975; 1976). However, on the basis of cosmogenic exposure dates that constrain its  
170 deposition to the ~~Middle to~~ Late Holocene it is now widely accepted to have been deposited by a rock-slope failure that  
171 experienced excess run-out (e.g. a rock avalanche). The source is a distinct, fault-bounded failure scar on the southern flank  
172 of Sgurr Mor, the highest peak of Beinn Alligin (Ballantyne, 2003; Ballantyne and Stone, 2004). The rock avalanche is  
173 comprised of large, poorly-sorted boulders and is calculated to comprise a total volume of 3.3 – 3.8 x 10<sup>6</sup> m<sup>3</sup>, equivalent to a  
174 mass of 8.3 – 9.5 Mt (Ballantyne and Stone, 2004). The source lithology is Late Precambrian Torridonian sandstone strata.  
175 The Torridonian sandstones are reddish or reddish brown terrestrial sedimentary rocks deposited under fluvial or shallow  
176 lake conditions (Stewart, 1982). The sandstones maintained a common origin throughout deposition (Stewart, 1982) and are  
177 thus largely consistent in mineralogy (dominated by quartz, and alkali and plagioclase feldspar) although there are some  
178 local variations in grain size (Stewart and Donnellan, 1992).

179 The <sup>10</sup>Be concentrations of three boulders used for cosmogenic nuclide exposure dating were internally consistent  
180 evidencing a single, catastrophic mass movement event which occurred 4.54 ± 0.27 ka (re-calculated from Ballantyne and  
181 Stone, 2004). Consequently, the boulders were very unlikely to have previously been exposed to cosmic rays or sunlight  
182 prior to transport and deposition. Moreover, the large size of the flat-topped boulders (>2 x 2 x 2 m) and lack of finer  
183 sediment matrix within the rock avalanche deposit, suggested that post-depositional movement or exhumation is unlikely.  
184 The Torridonian sandstones are hard, cemented rocks (Stewart, 1984; Stewart and Donnellson, 1992) susceptible to granular  
185 disintegration (e.g. Ballantyne and Whittington, 1987). Given its inland location, salt weathering is likely negligible.  
186 Kirkbride and Bell (2010) estimated edge-rounding rates of ~3.3 mm/ka for a suite of Torridonian sandstone boulder  
187 samples from a range of sites in NW Scotland under the warmer, wetter climates of the Holocene. A notably higher erosion  
188 rate of 12 mm/ka was specifically determined for the Beinn Alligin rock avalanche. Kirkbride and Bell (2010) suggest that  
189 this higher erosion rate, in comparison to the other sites, is likely due to inherited rock roundness caused by abrasion during  
190 the high-magnitude depositional event. Additionally, minor differences in lithology cannot be ruled out (e.g. Twidale, 1982;  
191 Ford and Williams, 1989). Consequently, we consider the range ~3.3 to 12 mm/ka as a reasonable estimation of the  
192 Holocene erosion rate of the Torridonian sandstone boulders that comprise the Beinn Alligin rock avalanche.

### 193 **4. Methods**

194 A total of six rock samples were taken from the Torridonian sandstones in NW Scotland (Fig. 1). Three samples were taken  
195 from three different road-cuttings of known age to calibrate the values of  $\mu$  and  $\overline{\sigma\phi_0}$ : ROAD01 (0.01 a), ROAD02 (57 a; Fig.  
196 S1a), ROAD03 (44 a; Fig. S1b). Three further samples were taken from flat-topped, angular boulders that were part of the  
197 Beinn Alligin rock avalanche deposit: BALL01, BALL02 and BALL03 (Fig. 1D). Portions of the original boulder or  
198 bedrock sample ~~Samples~~ were collected in the field in daylight and immediately placed into opaque, black sample bags. All  
199 samples were taken from surfaces perpendicular to incoming sunlight to ensure that the daylight irradiation geometry was  
200 similar between calibration and dating samples (cf. Gliganic et al. 2019).

#### 201 4.1 Luminescence measurements

202 To calculate the environmental dose-rate throughout burial for each sample (Table 1), U, Th and K concentrations were  
203 measured for ca. 80 g of crushed bulk sample using high-resolution gamma spectrometry. Internal dose-rates were calculated  
204 assuming an internal K-content of  $10 \pm 2$  % (Smedley et al. 2012) and internal U and Th concentrations of  $0.3 \pm 0.1$  ppm and  
205  $1.7 \pm 0.4$  ppm (Smedley and Pearce, 2016), in addition to the ~~using~~ measured average grain sizes for each sample. Cosmic  
206 dose-rates were calculated after Prescott and Hutton (1994). For measuring the luminescence depth profiles, sample  
207 preparation was performed under subdued-red lighting conditions to prevent contamination of the luminescence signal. Rock  
208 cores ~7 mm in diameter and up to 20 mm long were drilled into the rock surface using an Axminster bench-top, pillar drill  
209 equipped with a water-cooled, diamond-tipped drillbit (~9 mm diameter). Each core was sliced at a thickness of ~0.7 mm  
210 using a Buehler IsoMet low-speed saw equipped with a water-cooled, 0.3 mm diameter diamond-tipped wafer blade. All  
211 slices were then mounted in stainless steel cups for luminescence measurements.

212 Luminescence measurements were performed on a Risø TL/OSL reader (TL-DA-15) with a  $^{90}\text{Sr}/^{90}\text{Y}$  beta irradiation  
213 source. Heating was performed at  $1^\circ\text{C}/\text{s}$  and the rock slices were held at the stimulation temperature (i.e. 50, 150 and  $225^\circ\text{C}$ )  
214 for 60 s prior to IR stimulation to ensure all of the disc was at temperature before stimulating (cf. Jenkins et al. 2018). IRSL  
215 signals were detected in blue wavelengths using a photo-multiplier tube fitted with Schott BG-39 (2 mm thickness) and  
216 Corning 7-59 (2 mm thickness) filters. A MET-post-IR IRSL sequence (Table S1) was used to determine IRSL signals at  
217 three different temperatures (50, 150 and  $225^\circ\text{C}$ ) simultaneously ~~successively~~, hereafter termed the  $\text{IR}_{50}$ ,  $\text{pIRIR}_{150}$  and  
218  $\text{pIRIR}_{225}$  signals. OSL Luminescence depth profiles were determined for each core by measuring the natural signal ( $L_n$ )  
219 normalised using the signal measured in response to a 53 Gy test-dose ( $T_n$ ), hereafter termed the  $L_n/T_n$  signal. The IRSL  
220 signal was determined by subtracting the background signal (final 20 s, 40 channels) from the initial signal (0 – 3.5 s, 7  
221 channels). The large test-dose (53 Gy) was used to reduce the impact of thermal transfer/incomplete resetting of the IRSL  
222 signal between measurements (after Liu et al. 2016).

223  $D_e$  values were determined for the shallowest disc and the deepest disc from one core of each sample to quantify the  
224 natural residual dose and saturation limit ( $L_0$ , Eq. 1), respectively. Fading rates ( $g$ -values, Aitken 1985) were determined for  
225 three discs of each sample and normalised to a  $t_c$  of two days (Huntley and Lamothe 2001). The weighted mean and standard  
226 error of the  $g$ -values for all discs were  $3.7 \pm 0.4$  %/dec. ( $\text{IR}_{50}$ ),  $1.0 \pm 0.5$  %/dec. ( $\text{pIRIR}_{150}$ ) and  $1.0 \pm 0.5$  %/dec. ( $\text{pIRIR}_{225}$ ).

227 The large uncertainties on the individual  $g$ -values measured were derived from uncertainty in the fit of the data, which is  
228 typical of fading measurements (e.g. Smedley et al. 2016). The fading rates were in line with previous [measurements of](#)  
229 IRSL signals (e.g. Roberts 2012; Trauerstein et al. 2014; Kolb and Fuchs 2018). Lehmann et al. (2019a) performed  
230 sensitivity tests of the shape of the luminescence depth profiles ( $IR_{50}$ ) with a high and low  $g$ -value end-members and these  
231 simulations demonstrated that athermal loss of signal has a minimal impact upon the IRSL depth profile shape; thus,  
232 athermal loss (i.e. fading rates) was not considered in calculations.

233 Previous studies have shown that the  $IR_{50}$  signal bleached faster than the pIRIR signals (Smedley et al., 2015). To  
234 test the inherent bleaching rates of the feldspars in our samples, artificial bleaching experiments were performed on seven  
235 discs from all six samples (n.b. these experiments do not test for variations in light attenuation with depth). All previously-  
236 analysed discs were given a 105 Gy dose, then subjected to different exposure times in a solar simulator (0 m, 1 m, 10 m, 30  
237 m, 1 h, 4 h and 8 h) and the normalised luminescence signals ( $IR_{50}$ , pIRIR<sub>150</sub> and pIRIR<sub>225</sub>) were measured (Fig. S42). The  
238 results show some variations after 1 m of solar simulator exposure. However, luminescence signals reduced to 2 – 6 %  
239 ( $IR_{50}$ ), 6 – 11 % (pIRIR<sub>150</sub>) and 14 – 22 % (pIRIR<sub>225</sub>) of the unexposed light levels after 1 h and 1 – 2 % ( $IR_{50}$ ), 2 – 3 %  
240 (pIRIR<sub>150</sub>) and 4 – 7 % (pIRIR<sub>225</sub>) after 8 h. This indicates that within our samples the minerals emitting the IRSL signals  
241 (i.e. K-feldspar) have similar inherent bleaching rates [when exposed to longer durations of time \(i.e. > 8 h in the solar](#)  
242 [simulator\)](#).

#### 243 4.2 Rock composition

244 After luminescence measurements were performed, each rock slice (e.g. Fig. 2) was analysed to investigate potential changes  
245 in rock composition with depth (inferred by opacity [and grainsize](#)). The average down-core grainsize of each sample was  
246 measured under an optical microscope [using Infinity Analyze](#). [For each rock slice of an example core per sample, ten](#)  
247 [randomly-selected grains were measured and the mean and standard deviation grainsize were calculated per core and plotted](#)  
248 [against the core depths \(Fig. 3B\)](#). Down-core red-green-blue (RGB) values were determined for each sample to investigate  
249 whether there was any colour variation within the sample, and externally between samples; thus, providing a semi-  
250 quantitative tool to detect variability in rock opacity (Meyer et al. 2018). Raster images of RGB were obtained for each rock  
251 slice using an EPSON Expression 11000XL flatbed scanner at 1200 dpi resolution (e.g. Fig. S32). Mean and standard  
252 deviations of the RGB values (e.g. Fig. 3A) for each rock slice were calculated using the *raster* package in R (version 2.9-  
253 23; Hijmans, 2019).

## 254 5. Results

### 255 5.1 Luminescence depth profiles

256 The luminescence depth profiles ( $IR_{50}$ , pIRIR<sub>150</sub> and pIRIR<sub>225</sub>) (Fig. 4) record bleaching fronts caused by sunlight exposure  
257 for all of the known-age samples. The luminescence depth profile measured for core 3 of sample ROAD02 (Fig. 4  
258 [g-h,jG,H,J](#)) was inconsistent with cores 1 and 2, giving high standard deviation values for the  $IR_{50}$  (1.2), pIRIR<sub>150</sub> (1.1) and  
259 pIRIR<sub>225</sub> (0.9) signals; thus, core 3 was removed from subsequent analysis (likely sample preparation issues related to

drilling preservation of the weathered surface). The luminescence depth profiles for the remaining replicate cores for all three samples were broadly consistent within each rock sample with mean standard deviations ranging from 0.2 – 0.8.

The luminescence depth profiles (Fig. 4) for the IR<sub>50</sub> signal were consistent with the increasing sunlight exposure ages for ROAD01 (0.01 a), ROAD03 (44 a) and ROAD02 (57 a), with bleaching fronts at 2.50.75 mm, 4.500 mm and 4.76.5 mm, respectively (Fig. S54a). This indicated that the depth of the IR<sub>50</sub> bleaching front was dominated by exposure duration for the known-age samples as expected. Similarly, the pIRIR<sub>150</sub> and pIRIR<sub>225</sub> bleaching fronts were shallower in sample ROAD01 (0.754.5 mm) compared to ROAD02 and ROAD03 (2.5.00 – 33.500 mm), reflecting the younger exposure duration of ROAD01. However, the pIRIR<sub>150</sub> and pIRIR<sub>225</sub> bleaching fronts were at similar depths (23.75 and 3.00 mm and 2.005 and 2.50 mm respectively) for both ROAD02 (57 a) and ROAD03 (44 a). This suggests that either another factor is influencing light penetration with depth in these rocks (e.g. small differences in the orientation of the sampled rock faces; Fig. S1) or that the pIRIR signals cannot resolve between a 57 a and 44 a exposure history (difference of only 13 a). Note that the inferred models shown in Fig. 4 were fitted using the  $\overline{\sigma\phi_0}$  and  $\mu$  values included in each figure. See Section 5.2 for further explanation of the estimation of the model parameters.

The luminescence depth profiles measured for the unknown-age samples BALL02 and BALL03 using the IR<sub>50</sub>, pIRIR<sub>150</sub> and pIRIR<sub>225</sub> signals (Fig. 5) recorded bleaching fronts caused by sunlight exposure. Conversely, the luminescence depth profile for sample BALL01 had saturated IRSL signals throughout the core and did not display any evidence of IRSL signal resetting with depth (Fig. 5aA-Ce). A luminescence depth profile measured for a core drilled into the bottom surface (Bottom C1; Fig. 5Aa-eC) confirmed that the bottom surface of BALL01 was also saturated. The lack of a bleaching front in sample BALL01 is difficult to explain as the sample was taken in daylight and had seemingly identical characteristics to samples BALL02 and BALL03 (i.e. no lichen-cover or coatings preventing light penetration in the rock). Although all the samples were similar in colour/opacity (Fig. 3Aa), the surface of sample BALL01 was coarser grained than BALL02 and BALL03 (Fig. 2; Fig. 3Bb). Studies have shown that coarser grain sizes are more susceptible to mechanical weathering via grain detachment induced by chemical weathering (Israelli and Emmanuel, 2018); † Thus, although care was taken when sampling to mark the surface of the rock and to measure the length of the rock cores before and after slicing, it is possible that the luminescence depth profile (likely <10 mm based on BALL02 and BALL03) was lost during sampling and/or sample preparation due to the presence of a fragile weathering crust, potentially with a sub-surface zone of weakness (e.g. Robinson and Williams, 1987). Furthermore, field observations showed the presence of a rock pool on the surface of the boulder sampled for BALL01, which is not present on BALL02 and BALL03 (Fig. 1De); thus, there is also potential that the surface sampled for BALL01 had experienced enhanced chemical weathering via trickle paths draining the rock pool. These are commonly linked to a greater density of micro-cracks in the uppermost mm's-millimetres of the rock (Swantesson, 1989, 1992). Consequently, we did not derive exposure ages or erosion rates from BALL01. Where rock pools are likely on boulders, the highest rock surface should be sampled for luminescence techniques to avoid the potential for pooling or trickle paths.

## 293 5.2 Estimation of model parameters

294 To determine an apparent exposure age or erosion rate from the measured luminescence depth profiles, the variables that  
295 control the evolution of a luminescence depth profile in a rock surface must be parameterised; specifically, the dose-rate ( $\dot{D}$ )  
296 (see Section 4.1), saturation level ( $D_0$ ),  $\overline{\sigma\varphi_0}$  and  $\mu$ .  $D_0$  was determined experimentally from saturated dose-response curves  
297 measured for the deepest rock slices of each sample.  $\overline{\sigma\varphi_0}$  and  $\mu$  were calibrated using [Eq. \(1\)](#) and the known-age samples  
298 [\(ROAD01, ROAD02 and ROAD03\)](#) of similar, suitable rock composition as determined by the down-core profiles of RGB  
299 and grainsize (Section 4.2). [Note that  \$\dot{D}\$  is not considered in Eq. \(1\) but is used to determine an apparent exposure age or  
300 erosion rate and so needs to be measured for each sample \(see Section 2\).](#) Down-core RGB values for all samples were  
301 internally consistent (Fig. 3aA) as indicated by the relative standard deviation (RSD) range between 8 and 12 %. The down-  
302 core RGB values were also externally consistent between all samples (Fig. 3Aa), with the exception of the slightly darker-  
303 coloured sample ROAD01. However, measurements of grainsize (Fig. 3bB) showed that the known-age sample ROAD02  
304 ( $90 \pm 23 \mu\text{m}$ ) had a similar grainsize to the unknown-age samples BALL02 ( $73 \pm 18 \mu\text{m}$ ) and BALL03 ( $98 \pm 19 \mu\text{m}$ ),  
305 whereas ROAD01 ( $42 \pm 9 \mu\text{m}$ ) and ROAD03 ( $168 \pm 56 \mu\text{m}$ ) were finer and coarser grained, respectively. Given the  
306 similarity in colour and grain-size, it was considered most appropriate to calibrate  $\overline{\sigma\varphi_0}$  and  $\mu$  for the unknown age samples  
307 (BALL02 and BALL03) using known-age sample ROAD02.

308 The values of  $\overline{\sigma\varphi_0}$  and  $\mu$  were determined by fitting Eqn. (1) using the approach of Lehmann et al. (2019a). The  
309 inferred model (Eq. 1) had a good fit to the measured data for all samples and signals (Fig. 4) and  $\mu$  and  $\overline{\sigma\varphi_0}$  were calculated  
310 (Table 2; Fig. 6). [For ROAD01, the parameters determined using the IR<sub>50</sub> \( \$\mu = 3.2 \text{ mm}^{-1}\$ ,  \$\overline{\sigma\varphi\_0} = 2.80e^{-4} \text{ s}^{-1}\$ \), pIRIR<sub>150</sub> \( \$\mu =\$   
311  \$3.1 \text{ mm}^{-1}\$ ,  \$\overline{\sigma\varphi\_0} = 3.27e^{-5} \text{ s}^{-1}\$ \) and pIRIR<sub>225</sub> \( \$\mu = 3.0 \text{ mm}^{-1}\$ ,  \$\overline{\sigma\varphi\_0} = 2.88e^{-5} \text{ s}^{-1}\$ \) signals were broadly consistent. For ROAD02,  
312 the parameters differed between the IR<sub>50</sub> \( \$\mu = 2.1 \text{ mm}^{-1}\$ ,  \$\overline{\sigma\varphi\_0} = 6.67e^{-6} \text{ s}^{-1}\$ \), pIRIR<sub>150</sub> \( \$\mu = 1.5 \text{ mm}^{-1}\$ ,  \$\overline{\sigma\varphi\_0} = 1.73e^{-8} \text{ s}^{-1}\$ \) and  
313 pIRIR<sub>225</sub> \( \$\mu = 2.8 \text{ mm}^{-1}\$ ,  \$\overline{\sigma\varphi\_0} = 9.01e^{-8} \text{ s}^{-1}\$ \) signals, but the values for each signal were broadly similar to the equivalent  
314 values determined for ROAD03 using the IR<sub>50</sub> \( \$\mu = 2.7 \text{ mm}^{-1}\$ ,  \$\overline{\sigma\varphi\_0} = 1.56e^{-5} \text{ s}^{-1}\$ \), pIRIR<sub>150</sub> \( \$\mu = 1.5 \text{ mm}^{-1}\$ ,  \$\overline{\sigma\varphi\_0} = 3.80e^{-8} \text{ s}^{-1}\$ \)  
315 and pIRIR<sub>225</sub> \( \$\mu = 1.4 \text{ mm}^{-1}\$ ,  \$\overline{\sigma\varphi\_0} = 1.70e^{-8} \text{ s}^{-1}\$ \) signals. Given the similarity of  \$\overline{\sigma\varphi\_0}\$  and  \$\mu\$  determined using all three IRSL  
316 signals for ROAD02 and ROAD03 and the difference in grainsizes \(Fig. 3B\), it suggests that grainsize has a minimal impact  
317 upon the attenuation of light into a rock surface in comparison to other factors \(e.g. mineralogy, surficial coatings\). The  \$\mu\$   
318 values for samples ROAD01, ROAD02 and ROAD03 determined using the IR<sub>50</sub> signal in this study were comparable to  \$\mu\$   
319 values in existing literature for sandstones \[using K-feldspar\]\(#\) e.g.  \$\mu = 1.01 \text{ mm}^{-1}\$  where  \$\overline{\sigma\varphi\_0} = 6.80e^{-4} \text{ s}^{-1}\$  \(Sohbati et al. 2012\)  
320 and  \$3.06 \text{ mm}^{-1}\$  \(Ou et al. 2018\). For sample ROAD01,  \$\mu\$  and  \$\overline{\sigma\varphi\_0}\$  were similar for all three IRSL signals with large  
321 uncertainties \(Fig. 6Aa-eC\) which is likely related to the shorter exposure age of this sample \(0.01 a\). The finer grain size  
322 and darker rock opacity of sample ROAD01 in comparison to ROAD02 and ROAD03 likely explained the larger values of  \$\mu\$   
323 \(i.e. greater light attenuation with depth into the rock surface\).](#)

## 324 5.3 Apparent exposure ages and erosion rates

325 Luminescence exposure ages were determined from the luminescence depth profiles using  $\mu$  and  $\overline{\sigma\phi_0}$  derived from sample  
326 ROAD02 for each of the IRSL signals (Table 3). For BALL03, the  $IR_{50}$  ( $3787 \pm 103+5$  a<sup>+</sup>),  $pIRIR_{150}$  ( $2964 \pm 6+54$  a<sup>+</sup>) and  
327  $pIRIR_{225}$  ( $37062 \pm 469$  a<sup>+</sup>) signals all gave luminescence exposure ages in agreement within uncertainties. For BALL02, the  
328 three signals were inconsistent with one another. The  $pIRIR_{225}$  signal ( $27963 \pm 4830$  a<sup>+</sup>) was consistent with BALL03, but  
329 the  $IR_{50}$  ( $89 \pm 23$  a<sup>+</sup>) and  $pIRIR_{150}$  ( $7066 \pm 916$  a<sup>+</sup>) signals for BALL02 were younger than BALL03. All apparent exposure  
330 ages based on the different luminescence signals were at least one order of magnitude younger than the apparent exposure  
331 age based cosmogenic nuclide dating ( $4.54 \pm 0.27$  ka; Ballantyne and Stone, 2004). This was likely because erosion over  
332 time in this wet, temperate climate has removed material from the surface of the rock and created shallower luminescence  
333 depth profiles in comparison to a non-eroding profile; thus, the luminescence depth profile is dependent upon both exposure  
334 age and the erosion rate (Sohbati et al. 2018; Lehmann et al. 2019a).

335 To test whether erosion rates could be determined for the Beinn Alligin boulders from the luminescence depth  
336 profiles, we performed erosion rate modelling following the inversion approach of Lehmann et al. (2019) and constrained by  
337 the re-calculated cosmogenic nuclide age (Ballantyne and Stone, 2004). This approach defines an erosion history that  
338 follows a step function with an initial period of zero erosion, followed by an immediate increase to a constant erosion rate at  
339 a defined time. It attempts to recover parameter combinations (erosion rate and timing of erosion initiation) that are both  
340 consistent with the cosmogenic nuclide concentration and produce modelled luminescence profiles that match observations.  
341 For ~~sample~~-BALL02, both the  $IR_{50}$  and  $pIRIR_{150}$  signals suggested that the system had approached a steady-state with erosion  
342 rates of 66 mm/ka ( $IR_{50}$ ) and 9 mm/ka ( $pIRIR_{150}$ ) applied over time periods >73 a and 593 a, respectively. However, the  
343  $pIRIR_{225}$  signal suggested a transient erosion state, where the luminescence signal could be derived from numerous pairs of  
344 erosion rates and initiation times from a maximum erosion rate of 310 mm/ka over a minimum time interval of 4 a to a  
345 minimum erosion rate of 12 mm/ka over a minimum time interval of 90 a. All three IRSL signals from sample BALL03  
346 consistently suggested a system undergoing a transient response to erosion, which was consistent with the  $pIRIR_{225}$  signal of  
347 BALL02 (Fig. 7, Table 3). The  $IR_{50}$  signal for BALL03 derived a maximum erosion rate of 460 mm/ka over a minimum  
348 time interval of 3 a and a minimum erosion rate of 6 mm/ka over a minimum time interval of 231 a. The  $pIRIR_{150}$  signal for  
349 BALL03 derived a maximum erosion rate of 100 mm/ka over minimum time interval of 19 a and a minimum erosion rate of  
350 14 mm/ka over a minimum time interval of 137 a. The  $pIRIR_{225}$  signal for BALL03 derived a maximum erosion rate of 180  
351 mm/ka over a minimum time interval of 4 a and a minimum erosion rate of 11 mm/ka over a minimum time interval of 73 a.

352 At face value, the fit of the inferred erosion model to the experimental data for BALL02 using the  $IR_{50}$  (Fig. 5D)  
353 and  $pIRIR_{150}$  (Fig. 5E) signals is better than the equivalent fits for BALL02 using the  $pIRIR_{225}$  signal (Fig. 5F) and BALL03  
354 using the  $IR_{50}$  (Fig. 5G),  $pIRIR_{150}$  (Fig. 5H) and  $pIRIR_{225}$  (Fig. 5I) signals. In the latter cases, the inferred erosion model is  
355 shallower than the experimental data. This could suggest that the  $\overline{\sigma\phi_0}$  and  $\mu$  values were inaccurate, i.e. the attenuation of  
356 light with depth into the rock surface is lower in BALL02 ( $pIRIR_{225}$  signal) and BALL03 ( $IR_{50}$ ,  $pIRIR_{150}$  and  $pIRIR_{225}$   
357 signals) than estimated by ROAD02. A possible explanation for this is that the surface of the roadcut sampled by ROAD02

(Fig. S1a) was orientated slightly differently to the Beinn Alligin rock avalanche boulders sampled by BALL02 and BALL03 (Fig. 1D), relative to the incoming sunlight (e.g. Gliganic et al. 2019). However, if the orientation of the known-age roadcut samples was even slightly inconsistent with the unknown samples, we would expect these inconsistencies to manifest similarly in all three MET signals for BALL02 and BALL03, which was not observed here. A factor that is common to all the less wellpoorly fitting profiles that are less well fit by the inferred erosion model is that they determineddefine transient erosion ratesstates. This suggests that these surfaces experienced complex erosional histories over time whereby the erosion rate was time-varying. Consequently, it is possible that surficial weathering products may have changed in thickness and composition over time, which in turn could slightly vary the attenuation of light (Meyer et al. 2018; Luo et al. 2018), meaning that the calibration of  $\overline{\sigma\phi_0}$  and  $\mu$  from ROAD02 here introduced uncertainty into the inferred erosion model as it was not time-varying. It is also possible that sample-specific measurements of  $\overline{\sigma\phi_0}$  and  $\mu$  (e.g. Ou et al. 2018), rather than calibration from known-age samples, could reduce the uncertainty introduced by time-varying light attenuation. However, further investigation is required into the physical mechanisms of time-varying light attenuation in the context of surficial weathering and subsequent erosion, and the impacts upon inferred transient erosion rates.

## 6. Discussion

### 6.1 Luminescence depth profiles at for the Beinn Alligin rock avalanche

Despite the similarity in rock opacity, grain-size, aspect and exposure history, the luminescence depth profiles for samples BALL02 and BALL03 from the Beinn Alligin rock avalanche were inconsistent (Fig. 5). We consider it unlikely that this lack of consistency was caused by local variations in erosion rates (e.g. due to microclimate, aspect etc; Hall et al. 2005, 2008) as there were discrepancies between all three IRSL signals of BALL02. We would expect local erosion rate variations between samples to be consistently recorded across each of the IRSL signals, assuming the model parameterisation ( $\mu$  and  $\overline{\sigma\phi_0}$ ) were accurate. Specifically, and with all other things being equal, a locally-variable erosion rate would translate the bleaching front(s) closer to the rock surface by a proportionally consistent amount for each signal of a given sample.

Analysis of the rock opacity with depth (Section 4.2; Meyer et al. 2018) showed that sample BALL02 was more positively skewed towards darker colours than ROAD02 and BALL03 (Fig. S32, S34), with higher surficial values caused by Fe-staining. Fe-staining can occur on rock surfaces with seasonal rock pools and trickle paths (Swantesson, 1989, 1992). The presence of a thin Fe-coating (<1 mm) on the rock surface would have changed the intensity and wavelength of the net daylight flux received by individual grains (e.g. Singhvi et al., 1986; Parish, 1994) and likely increased light attenuation with depth (e.g. Meyer et al. 2018; Luo et al. 2018). Consequently, the parameterisation of  $\mu$  and  $\overline{\sigma\phi_0}$  derived from sample ROAD02 would be inaccurate for BALL02. Interestingly, the similarity between BALL02 and BALL03 for the pIRIR<sub>225</sub> signal suggests that the presence of an Fe-coating altered may have preferentially attenuated the wavelengths that influence the attenuation of the IR<sub>50</sub> and pIRIR<sub>150</sub> signals to a lesser extent than, and not the pIRIR<sub>225</sub> signal, but the reasons for this requires further investigation. The application of the MET-pIRIR rather than just the stand-alone IR<sub>50</sub> signal protocol

391 provided a major advantage as it identified samples where the parameterisation of  $\mu$  and  $\overline{\sigma\phi_0}$  from known-age samples was  
392 complicated by factors such as surficial weathering coatings. Beyond this, it is possible that the MET-pIRIR protocol may be  
393 useful in identifying complex burial or exposure histories of rocks, similar to those that have been reported in previous  
394 studies but solely using the IR<sub>50</sub> signal (e.g. Freiesleben et al. 2015; Brill et al. 2021). There is also potential to explore  
395 whether the different temperature IRSL signals of the MET protocol record different states of erosion (i.e. steady or transient  
396 states) within the same rock surface, whereby the post-IR IRSL signals that are attenuated greater would be more susceptible  
397 to transient states of erosion in comparison to the lower temperature signals, which measure luminescence depth profiles to  
398 greater depths within the rock surface.

399 The boulders from the Beinn Alligin rock avalanche have been subject to a temperate climate for the last ~4 ka. The  
400 luminescence depth profiles from the boulders demonstrated that on these timeframes and under these climatic conditions the  
401 technique was an erosion-meter, rather than a chronometer, as expected (Sohbati et al. 2018; Lehmann et al. 2019a).  
402 Lehmann et al. (2018<sup>9a</sup>) noted that two of their samples, uncorrected for erosion, gave apparent luminescence exposure ages  
403 of ca. 640 a and <1 a compared to apparent TCN-cosmogenic nuclide ages of ca. 16.5 ka and 6.5 ka, respectively. It has thus  
404 been inferred that erosion rates >1 mm/ka can make interpretation of luminescence depth profiles in terms of an exposure age  
405 difficult without accurately constraining the erosion rate (Sohbati et al., 2018; Lehmann et al., 2018). This is consistent with  
406 the underestimation of luminescence exposure ages measured here for the Beinn Alligin rock avalanche (Table 3), which  
407 have been independently-dated to  $4.54 \pm 0.27$  ka using cosmogenic nuclides (Ballantyne and Stone, 2004). Consequently,  
408 luminescence depth profiles for the Beinn Alligin rock avalanche can only be inferred in terms of erosion rates.

## 409 **6.2 Luminescence as an erosion-meter**

410 The numerical approach of Lehmann et al. (2019a) exploits the different sensitivities of the luminescence (short-term) and  
411 cosmogenic nuclide (longer-term) techniques to erosion to infer erosion histories (steady state and transient over time) for  
412 rock surfaces. Their modelling shows that the higher erosion rates (>100 mm/ka) can only be sustained over shorter time  
413 durations (up to decadal) while at the same time being consistent with cosmogenic nuclide measurements. For BALL03,  
414 transient erosion rates were derived using the IR<sub>50</sub> (6 - 460 mm/ka), pIRIR<sub>150</sub> (14 - 100 mm/ka) and pIRIR<sub>225</sub> (11 - 180  
415 mm/ka) signals. These modelled transient erosion rates were broadly comparable to erosion rates inferred from luminescence  
416 depth profiles over comparable timeframes in previous studies: (i) rates between  $<0.038 \pm 0.002$  and  $1.72 \pm 0.04$  mm/ka for  
417 glacial boulders and landslides (granite gneiss, granodiorite and quartzite) in the Eastern Pamirs, China (Sohbati et al. 2018);  
418 and (ii) between  $3.5 \pm 1.2$  mm/ka and  $4,300 \pm 600$  mm/ka for glacially-modified, granitic bedrock in the French Alps  
419 (Lehmann et al., 2019b). This latter study modelled higher erosion rates (>100 mm/ka) over timescales from  $10^1$  to  $10^3$  a and  
420 lower erosion rates (<100 mm/ka) over longer time scales of  $10^3$  to  $10^4$  a. However, this comparison between modelled  
421 erosion rates does not account for the primary role that lithology has on weathering (e.g. Twidale, 1982; Ford and Williams,  
422 1989). The sampled boulders in our study were composed of Torridonian sandstone, which has been reported to undergo  
423 granular disintegration (e.g. Ballantyne and Whittington, 1987), particularly around edges, and thus may have experienced

424 higher erosion rates than the crystalline rocks (e.g. gneiss, granite) used in the studies of Sohbaty et al. (2018) and Lehmann  
425 et al., 2019b.

426 A major advantage of applying this new erosion-meter technique to boulders of the Beinn Alligin rock avalanche  
427 was the existing constraints on Holocene erosion rates (~3.3 to 12 mm/ka) for Torridonian sandstones in NW Scotland  
428 inferred from boulder edge roundness measurements (Kirkbride and Bell, 2009). The long-term erosion rates inferred from  
429 luminescence depth profiles were consistent with the estimates provided by measuring the boulder-edge roundness, when  
430 considering the differing approaches and assumptions of each method. Firstly, the sampling approach for the luminescence  
431 depth profiles targeted the flat-top surface of the boulders where granular disintegration would have been reduced relative to  
432 the boulder edges and corners. Thus, the boulder-edge roundness based erosion rates provided an upper constraint on the  
433 long-term erosion rate experienced by the boulders. Finally, the boulder-edge roundness measurements assumed steady-state  
434 erosion and could not identify the potential for a transient state of erosion, whereas the approach of Lehmann et al. (2019a,b)  
435 inferred some transient state of erosion (Table 3). Consequently, it is notable that the lower range of the transient erosion  
436 rates derived here using the IR<sub>50</sub> (6 - 460 mm/ka), pIRIR<sub>150</sub> (14 - 100 mm/ka) and pIRIR<sub>225</sub> (11 - 180 mm/ka) signals were  
437 broadly consistent with the steady-state erosion rate derived from boulder edge roundness measurements for the Torridonian  
438 sandstones (in the range of ca. 3.3 to 12.0 mm/ka). Lehmann et al. (2019b) noted that their modelled steady-state erosion  
439 rates were one to two orders of magnitude higher than suggested by a global compilation of bedrock surface erosion rates  
440 based on <sup>10</sup>Be (Portenga and Bierman, 2011), and measurements of upstanding, resistant lithic components (ca. 0.2 – 5.0  
441 mm/ka) in crystalline rock surfaces in Arctic Norway (André, 2002). The authors inferred that shorter-term erosion rates  
442 derived from luminescence measurements were higher than the longer-term averages due to the stochastic nature of  
443 weathering impacting upon shorter-term erosion rates, this is also suggested by the data presented here. These stochastic  
444 processes (i.e. varying over time) will be controlled by the in-situ weathering rates, which provided the material for erosion.  
445 For bare rock surfaces in wet, temperate climates, weathering rates are primarily driven by rock-type and moisture  
446 availability (i.e. precipitation) (Hall et al. 2012; Swantesson, 1992). The Torridonian sandstones are hard, cemented rocks  
447 (Stewart, 1984; Stewart and Donnellson, 1992) susceptible to granular disintegration (e.g. Ballantyne and Whittington,  
448 1987), which may have been stochastic in nature due to changing moisture availability for chemical weathering over time  
449 (Hall et al. 2012; Swantesson, 1992). Although ~~the~~ Torridonian sandstones is-are unlikely to be prone to frost shattering due  
450 to ~~its-their~~ low permeability and porosity (Lautridou, 1985; Hudec 1973 in Hall et al. 2012), cracks, faults and joints in the  
451 rock may have facilitated stochastic physical weathering (Swantesson 1992; Whalley et al. 1982), but little field evidence of  
452 this was preserved.

453 The modelled erosion histories that we have calculated here using the luminescence erosion-meter for samples  
454 BALL02 and BALL03 would have had a minimal effect upon the cosmogenic nuclide exposure age ( $4.54 \pm 0.27$  ka;  
455 Ballantyne and Stone, 2004). Only the steady-state erosion rate of 66 mm/ka inferred for BALL02 using the IR<sub>50</sub> signal,  
456 when applied for durations exceeding 1 ka, would ~~have increase d~~ the exposure age to any great degree. For example, when

457 the steady-state erosion rate of 66 mm/ka was applied for 0.1 ka, the corrected cosmogenic nuclide exposure age would have  
458 been 4.58 ka and, when the same erosion rate was applied for 1 ka it would have been 4.99 ka; these corrected ages were  
459 consistent within  $\pm 2 \sigma$  uncertainties of the uncorrected age of  $4.54 \pm 0.27$  ka (reported at  $1 \sigma$ : Ballantyne and Stone, 2004).  
460 The higher, transient erosion rates inferred for BALL03 were all applied for such a short period of time (e.g. Table 3) that  
461 they had a minimal effect on the cosmogenic nuclide exposure age.

462 Based on the long-term erosion rates derived here, the boulder sampled for BALL02 would have lost a total of 300  
463 mm ( $IR_{50}$ ), 41 mm ( $pIRIR_{150}$ ) and 54 mm ( $pIRIR_{225}$ ) from the surface over 4.54 ka, while the long-term erosion rates  
464 determined for BALL03 suggested that the boulder surface would have lost 27 mm ( $IR_{50}$ ), 64 mm ( $pIRIR_{150}$ ) and 50 mm  
465 ( $pIRIR_{225}$ ). All of these values (except for the  $IR_{50}$  signal of BALL02) were broadly consistent with field observations of  
466 quartz protrusions on the surface of boulders  $>2 \times 2 \times 2$  m that were densely distributed within the rock avalanche feature  
467 (Fig. 1). Alternatively, the maximum (shorter-term) erosion rate end members of the transient erosion histories would have  
468 removed 1407 mm (BALL02,  $pIRIR_{225}$ ), 2088 mm (BALL03,  $IR_{50}$ ), 454 mm (BALL03,  $pIRIR_{150}$ ) and 817 mm (BALL03,  
469  $pIRIR_{225}$ ) from the boulder surface over the 4.54 ka. These large values were inconsistent with field evidence and so  
470 indicative of the transient state of erosion where high erosion rates were only sustained over short periods of time.

### 471 472 **6.3 Late Holocene erosion history**

473 The transient state of erosion inferred by the rock luminescence measurements reflected the stochastic nature of erosion over  
474 the last 4 ka, where a lower time-averaged erosion rate was interrupted by discrete intervals of higher time-averaged erosion  
475 rates. Rock weathering would have been dependent upon a variety of factors, primarily rock type and climate (Merrill 1906).  
476 The main constituents of the Torridonian sandstones are quartz, alkali and plagioclase feldspar (mostly albite), with  
477 precipitated quartz cementing the rock being resistant to chemical weathering (Stewart and Donnellan, 1992). However, the  
478 red colouring of the sandstones represents the presence of Fe within the rock (Stewart and Donnellan, 1992), which is prone  
479 to chemical weathering via oxidation and reduction. Field evidence of quartz grain protrusions on the rock surfaces (Fig. 1)  
480 indicated that granular disintegration, rather than flaking or shattering, was the likely weathering process that produced  
481 material for erosion on these hard boulders (e.g. Swantesson, 1992). This is also supported by a lack of shattered material  
482 surrounding the large sampled boulders (and in fact on much of the Beinn Alligin rock avalanche deposit), despite the  
483 presence of dense, low-level vegetation surrounding the boulders (e.g. Fig. S6). Granular disintegration has been reported as  
484 responsible for much of the general microweathering in the temperate climate of Southern and Central Sweden during the  
485 Holocene (e.g. Swantesson, 1992).

486 Given the coupling between precipitation, ~~mean annual~~ temperature and erosion (e.g. Reiners et al., 2003; Portenga  
487 and Bierman, 2011), the stochastic processes producing transient erosion can relate to varying environmental conditions  
488 (Hall et al. 2012; Swantesson, 1992; Whalley et al. 1982). In an environment where moisture is abundant due to high  
489 precipitation rates (e.g. for NW Scotland, annual precipitation rates between 1981 and 2010 were ca. 2,300 mm/a; Met

Office, 2021), chemical weathering dominates: this is, as also reported for Holocene weathering processes in Sweden (Swantesson, 1989, 1992). Moisture availability, rather than temperature, is the limiting factor as studies have reported the presence of chemical weathering in natural settings subject to sub-zero temperatures (e.g. northern Canada, Hall, 2007; Antarctica, Balke et al. 1991). Proxy evidence from across the British Isles records variability in temperature and precipitation rates over the last 4.5 ka, where key increases in precipitation occurred at 2,750, 1,650 and 550 cal. years BP correlated to Bond cycles (Charman, 2010). Thus, the transient erosion rates measured from boulders of the Beinn Alligin avalanche were potentially a representation of the fluctuations in moisture availability experienced over the last 4.5 ka. Such processes can only be inferred from luminescence depth profiles as they are sensitive to changing erosion on shorter timeframes than all other techniques.

## 7. Conclusion

This study applies ~~the~~ new rock luminescence techniques to a well-constrained test scenario provided by flat-topped boulders from the Beinn Alligin rock avalanche in NW Scotland (a wet, temperate climate), which are lithologically consistent (Torridonian sandstones), have known-age road-cuts for parameterisation of  $\mu$  and  $\overline{\sigma\phi_0}$ , have known cosmogenic nuclide exposure ages ( $4.54 \pm 0.27$  ka) and independently-derived Holocene erosion rates (ca. 3.3 to 12.0 mm/ka). Applying the rock luminescence techniques for exposure dating underestimated the cosmogenic nuclide ages for the Beinn Alligin rock avalanche expected due to high erosion rates (as supported by field evidence of quartz grain protrusions on the rock surfaces). Alternatively, the erosion rates determined were consistent with expected rates that were independently measured in the field from boulder-edge roundness when considering the relative timescales of the time-averaged erosion rates. The findings show that the luminescence erosion-meter has the resolution and sensitivity required to detect transient erosion of boulders over the last 4.5 ka. The transient erosion rates, reflecting the stochastic nature of erosional processes in the wet, temperate region of NW Scotland, likely in response to the known fluctuations in moisture availability (and to a lesser extent temperature), which control the extent of chemical weathering. This study demonstrates that the luminescence erosion-meter has huge potential for inferring erosion rates on sub-millennial scales for both steady-state and transient states of erosion (i.e. stochastic processes), which is currently impossible with other techniques. Larger sample populations and careful sampling of rock surfaces (avoiding the potential for rock pools and trickle paths) will likely be key for accurate measurements of landscape-scale erosion, and the use of a MET-pIRIR protocol (50, 150 and 225 °C) is advantageous as it can identify samples suffering from ~~the~~ complexities that would not have been observed using only the standard IRSL signal measured at 50 °C, such as that introduced by within-sample variability (e.g. surficial coatings).

## Author contributions

RS, DS and RSJ were involved in project conception. RS, DS, RSJ and SB performed the field sampling. RS, DS, JB and GJ performed the measurements, analysis and interpretations. All authors contributed to the writing of the manuscript, including the preparation of figures.

524 **Acknowledgments**

525 Field and laboratory work was funded by Durham University Department of Geography Research Development Fund to DS.  
 526 The rock luminescence equipment in the Liverpool Luminescence Laboratory was funded by a Royal Society Research  
 527 Grant (RG170194) to RKS. DS is supported by a NERC Independent Research Fellowship NE/T011963/1. We thank  
 528 Benjamin Lehmann, an anonymous reviewer and the Associate Editor Jim Feathers for their constructive comments which  
 529 improved this manuscript.

Figure 3. (A) RGB values (0 = black and 255 = white) and (B) grainsize for each sample, calculated as the mean ( $\pm$  standard deviation) of the slices at each depth in all of the replicate cores analysed. Note that the RGB values and grainsize measurements were not derived from exactly the same cores, but example cores for each sample.

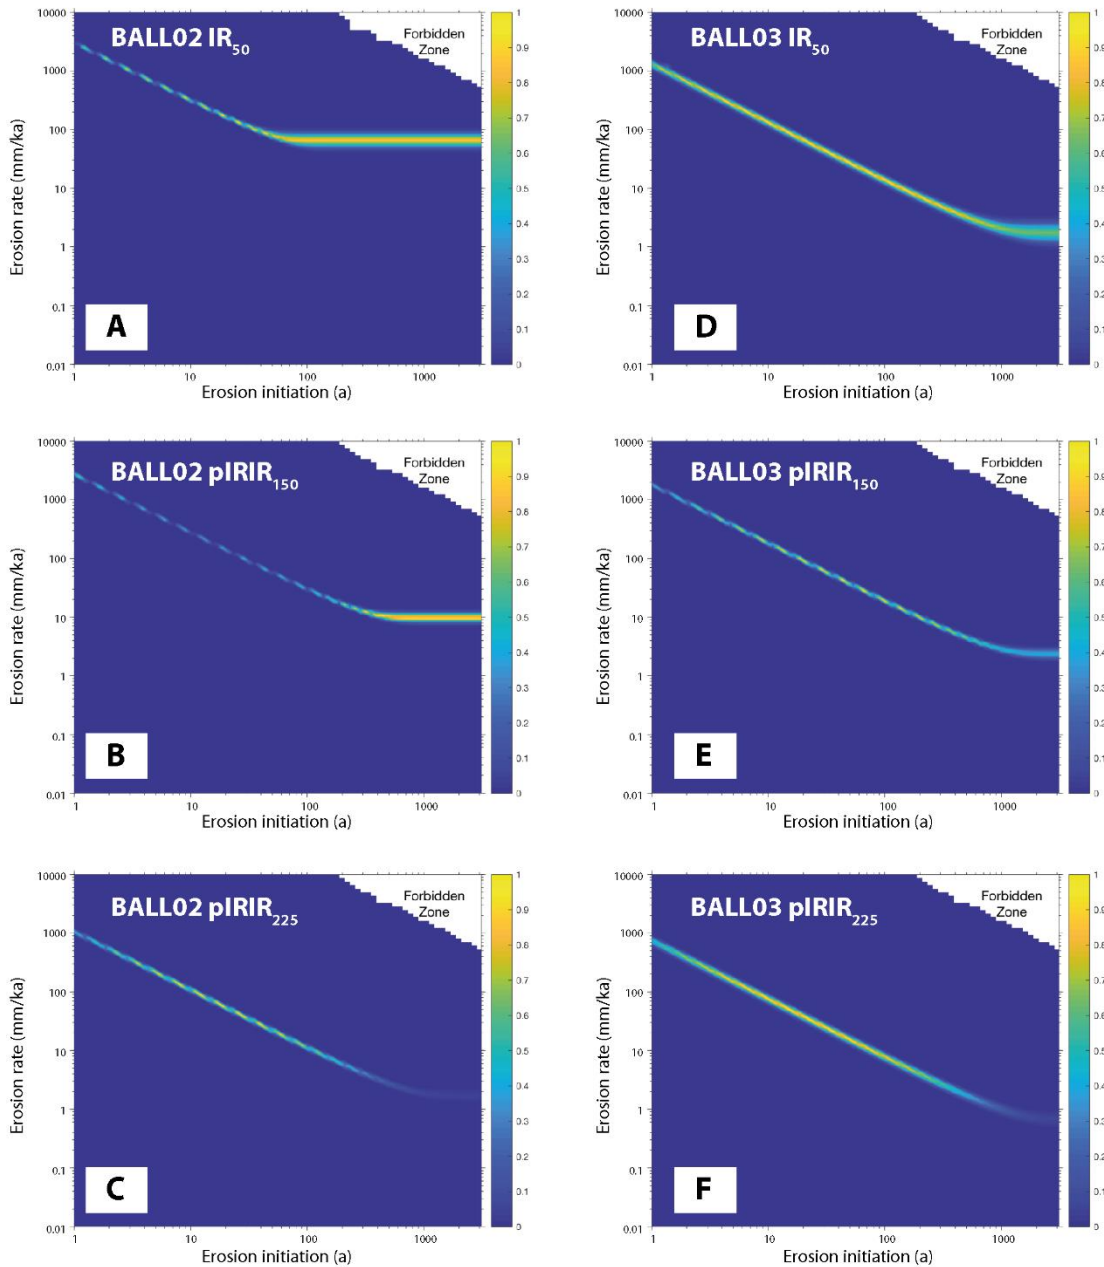

718  
719 **Figure 4.** Presented in age-order are the IRSL-depth profiles for each of the three replicate cores analysed per sample using the  
720 **IR<sub>50</sub>** (A,D,G), **pIRIR<sub>150</sub>** (B,E,H) and **pIRIR<sub>225</sub>** (C,F,I) signals for samples **ROAD01** (0.01 a; A-C), **ROAD03** (44 a; D-F) and  
721 **ROAD02** (57 a; G-I). All of the raw  $L_n/T_n$  data presented in this figure (Table S2-S4) were normalised individually for each core,  
722 and subsequent analysis uses the data in this format. The black line shown is the inferred model that was fitted to derive the  
723 corresponding  $\sigma\phi_0$  and  $\mu$  values included in each figure. The dotted lines show the corresponding fits modelled using the  $\pm 1\sigma$   
724  $\sigma\phi_0$  and  $\mu$  values (Table 2). Note that core 3 of ROAD02 was not considered for fitting.

726  
 727 **Figure 5.** IRSL-depth profiles for each replicate cores analysed using the IR<sub>50</sub> (A,D,G), pIRIR<sub>150</sub> (B,E,H) and pIRIR<sub>225</sub> (C,F,I)  
 728 signals for samples BALL01 (A-C), BALL02 (D-F) and BALL03 (G-I). All of the raw  $L_n/T_n$  data (Table S5-S7) were normalised  
 729 individually for each core, and subsequent analysis uses the data in this format. The dashed line is the inferred erosion model for  
 730 each luminescence depth profile derived from the probability distributions shown in Fig. 7, where erosion rates are included in  
 731 Table 3.

732

**Figure 7. Probability distributions inverted from the respective plots of luminescence depth profiles derived from the inversion results (using the approach of Lehmann et al. 2019a) for samples BALL02 (A-C) and BALL03 (D-F) using the IR<sub>50</sub> (A,D), pIRIR<sub>150</sub> (B,E) and pIRIR<sub>225</sub> (C,F) signals. The x-axis plots the time interval of the erosion rate initiation. Forbidden zones define the range of solutions with high erosion rates and durations that are not feasible within the bounds of the experimental <sup>10</sup>Be and luminescence data.**

Table 1. Luminescence results for the rock slices analysed in this study. Environmental dose-rates were determined using high-resolution gamma spectrometry. The dose-rates were calculated using the conversion factors of Guerin et al. (2011) and alpha (Bell, 1980) and beta (Guerin et al. 2012) dose-rate attenuation factors. An internal K-content of  $10 \pm 2\%$  (Smedley et al. 2012) and internal U and Th concentrations of  $0.3 \pm 0.1$  ppm and  $1.7 \pm 0.4$  ppm (Smedley and Pearce, 2016) were used to determine the internal alpha and beta dose-rates. An  $a$ -value of  $0.10 \pm 0.02$  (Balescu and Lamothe, 1993) was used to calculate the alpha dose-rates. Cosmic dose-rates were determined after Prescott and Hutton (1994). Dose-rates were calculated using the Dose Rate and Age Calculator (DRAC; Durcan et al. 2015). Grain size was measured by randomly selecting grains in the rock slices for each sample and calculating  $\pm 1$  standard deviation around the mean grain size.

Sample	Grain size ( $\mu\text{m}$ )	U (ppm)	Th (ppm)	K (%)	Internal alpha dose- rate (Gy/ka)	Internal beta dose- rate (Gy/ka)	External alpha dose- rate (Gy/ka)	External beta dose- rate (Gy/ka)	External gamma dose-rate (Gy/ka)	External cosmic dose-rate (Gy/ka)	Total dose- rate (Gy/ka)
BALL02	56-91	1.02 $\pm$ 0.15	4.85 $\pm$ 0.28	1.73 $\pm$ 0.29	0.14 $\pm$ 0.04	0.27 $\pm$ 0.06	0.21 $\pm$ 0.05	1.62 $\pm$ 0.00	0.78 $\pm$ 0.08	0.31 $\pm$ 0.03	3.32 $\pm$ 0.12

## Supplementary material: Smedley et al.

### Erosion rates in a wet, temperate climate derived from rock luminescence techniques

Fig. S1. Photographs of the known-age roadcut sections sampled for ROAD02 (a) and ROAD03 (b) constrained to 57 a and 44 a, respectively.

Fig. S2. Normalised luminescence signal remaining for individual discs from each sample after a given dose of 105 Gy and subsequent exposure to the solar simulator (0 m, 1 m, 10 m, 30 m, 1 h, 4 h and 8 h). Note that each disc had already been analysed for the natural luminescence signal.

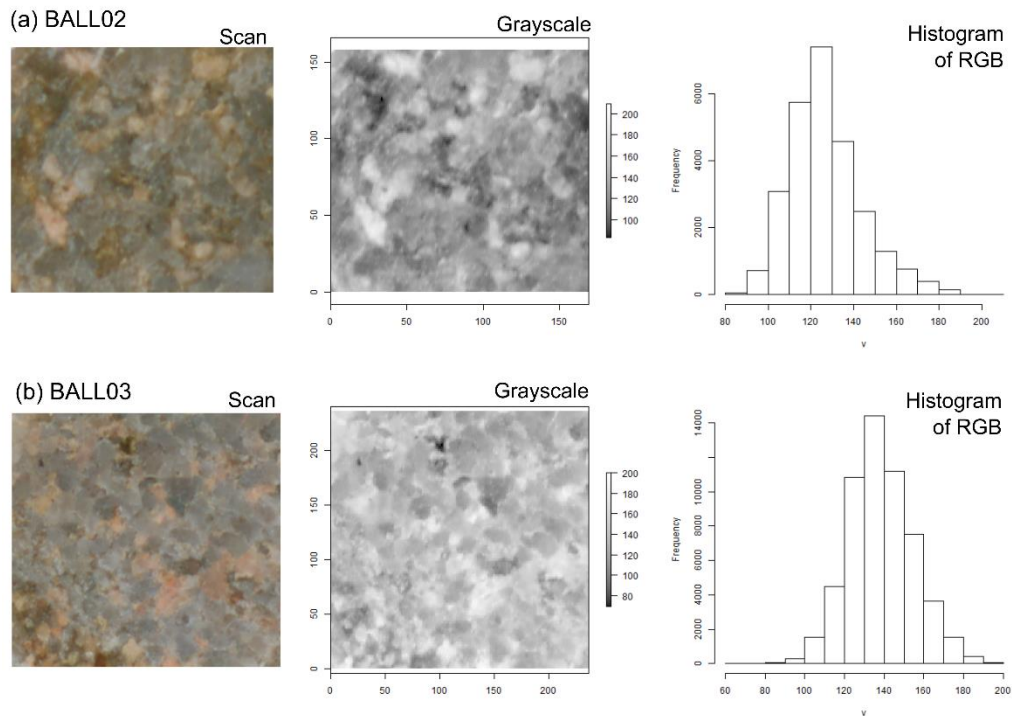

Fig. S3. Examples of true-colour and grayscale images for example slices of samples BALL02 and BALL03 using the EPSON Expression 11000XL flatbed scanner.

Fig. S4. Analysis of RGB values with depth for samples ROAD02, BALL02 and BALL03: (a) skewness of the pixel values for each images; (b) percentage of RGB values that are  $\leq 100$  (i.e. dark coloured).

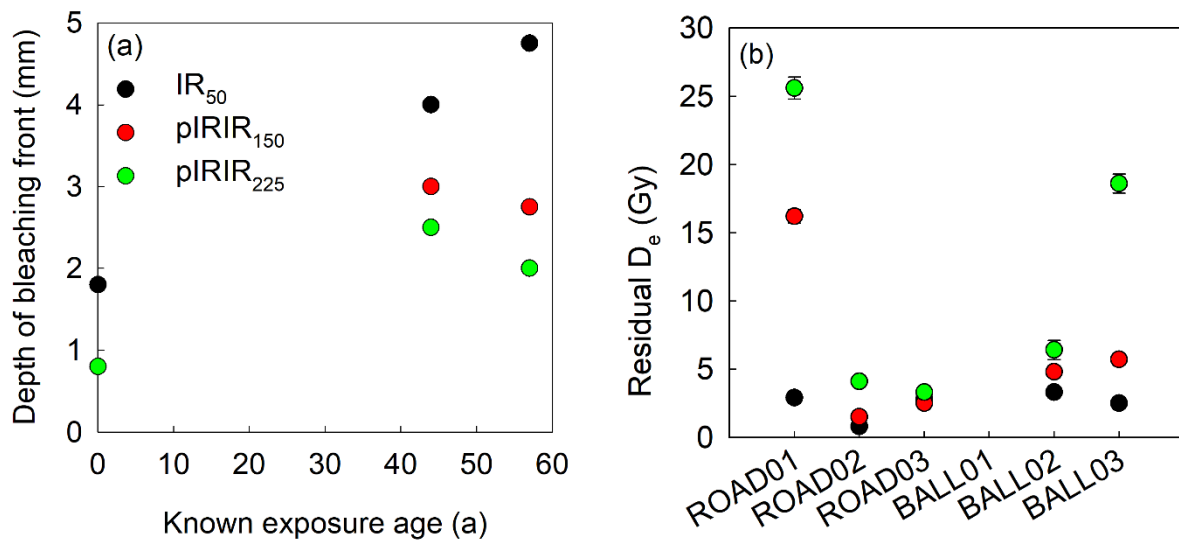

Fig. S5. (a) Depth of bleaching fronts for the known-age samples ROAD01 (0.01 a), ROAD02 (57 a) and ROAD03 (44 a). Note that the depth of the pIRIR<sub>150</sub> and pIRIR<sub>225</sub> bleaching fronts were identical for ROAD01 (0.01 a known-age sample). (b) Residual D<sub>e</sub> values determined for the surface slice (0-1 mm depth) of each sample. Note that sample BALL01 is not plotted on this figure as the residual D<sub>e</sub> values were large for all the IRSL signals: IR<sub>50</sub> ( $477.5 \pm 20.7$  Gy), pIRIR<sub>150</sub> ( $574.6 \pm 36.5$  Gy) and pIRIR<sub>225</sub> (could not be interpolated on to the dose-response curve).

Fig. S6. Photograph of the Beinn Alligin rock avalanche to illustrate the nature of the area surrounding the sampled boulders, which includes dense vegetation, the small-scale topography of the boulders and little evidence of shattered material.

Table S1. Multi-elevated temperature post- IR IRSL sequence used for analysis.

Step	Procedure
1	Natural or regenerative dose
2	Preheat 250 °C for 100 s
3	IR LEDs 50 °C for 200 s
4	IR LEDs 150 °C for 200 s
5	IR LEDs 225 °C for 200 s
6	Test-dose 53 Gy
7	Preheat 250 °C for 100 s
8	IR LEDs 50 °C for 200 s
9	IR LEDs 150 °C for 200 s
10	IR LEDs 225 °C for 200 s
11	IR LEDs 290 °C for 200 s

Table S4. Raw  $L_n/T_n$  data used for fitting sample ROAD03 in Fig. 4D-F.

Depth (mm)	Core 1						Core 2						Core 3					
	IR <sub>50</sub>		pIRIR <sub>150</sub>		pIRIR <sub>225</sub>		IR <sub>50</sub>		pIRIR <sub>150</sub>		pIRIR <sub>225</sub>		IR <sub>50</sub>		pIRIR <sub>150</sub>		pIRIR <sub>225</sub>
