Abstract. An optimal lighting setting for the darkroom laboratory is fundamental for the accuracy of luminescence dating results. Here, we present the lighting setting implemented in the new Luminescence Dating Research Laboratory at Stony Brook University, USA. In this study, we performed spectral measurements on different light sources and filters. Then, we measured the optically stimulated luminescence (OSL) signal of quartz and the infrared stimulated luminescence (IRSL) at 50°C (IR₅₀) as well as post-IR IRSL at 290°C (pIR-IR₂₉₀) signal of potassium (K)-rich feldspar samples exposed to various light sources and durations.

Our ambient lighting is provided by ceiling fixtures, each equipped with a single orange light-emitted diode (LED). In addition, our task-oriented lighting, mounted below each wall-mounted cabinet and inside the fume hoods, is equipped with a dimmable orange LED stripline.

The ambient lighting, delivering 0.4 lux at the sample position, induced a loss of less than 5% (on average) in the quartz OSL dose after 24 h of exposure, and up to 5% (on average) in the IR₅₀ dose for the K-rich feldspar samples, with no measurable effect on their pIR-IR₂₉₀ dose. The fume hood lighting, delivering 1.1 lux at the sample position, induced a dose loss of less than 5% in quartz OSL and K-rich feldspar IR₅₀ doses after 24 h of exposure, with no measurable effect on their pIR-IR₂₉₀ dose. As light exposure during sample preparation is usually less than 24 h, we conclude that our lighting setting is suitable for luminescence dating darkrooms, it is simple, inexpensive to build, and durable.

1 Introduction

Luminescence dating techniques enable evaluation of the time that has elapsed since crystallized mineral grains, such as quartz and feldspar, were last exposed to sunlight or high temperature. Hence, a fundamental requirement of the method is that the light-sensitive traps in mineral grains must have been entirely emptied in the past and remained unexposed to light until laboratory measurement (Aitken, 1998). During sample collection in the field and sample preparation in the laboratory, precautions should be taken to preserve the integrity of the samples using controlled lighting conditions; otherwise, there is a severe risk of reducing the dating signal (i.e., luminescence signal) and hence the apparent age (i.e., deposition time) of the mineral grains. For quartz grains, the shorter wavelengths (less than 360 nm) are most effective in evicting electrons from traps. For K-rich feldspar grains, the bleaching resonance is centered at 860 nm. For quartz and feldspar grains, dim lighting conditions in the orange-yellow to red wavelength provide minimal signal loss over a limited time (Aitken, 1998). Within this

31 large wavelength range, each luminescence dating laboratory worldwide defines its lighting conditions. In fact, only a few
32 laboratories have reported measurements of their lighting conditions (e.g., Spooner, 2000; Huntley and Baril, 2002, Lindvall
33 et al., 2017; Sohbati et al., 2017, 2021) and their effect on the mineral samples.

34 Here we report on the lighting conditions implemented in the new Luminescence Dating Research Laboratory at Stony Brook
35 University. First, we performed spectral measurements on different light sources and filters. Then, we measured the dose loss
36 of quartz and potassium (K)-rich feldspar samples after exposure to various light sources and times.

37 **2 Samples and Instrumentation**

38 Spectral measurements were performed using a Qmini Wide VIS (AFBR-S20M2WV) spectrometer with a spectral range of
39 212–1035 nm (sensitivity optimized at ~500 nm) and a spectral resolution at 1.5 nm equipped with an optic fiber P400-1-UV-
40 VIS400. The calibration of the spectrometer was performed in May 2019. All spectra were measured over a total integration
41 time of 2 s. The amount of light on the laboratory benchtops was measured with a luxmeter Dr.meter LX1330B digital
42 illumination/light meter.

43 In this study we used two quartz samples and two feldspar samples. One of the quartz sample is the calibration
44 quartz (180-250 μm , batch #118 and #123; Hansen et al., 2015). The second quartz sample (SB27) was collected from the
45 middle palaeolithic site of Oscurusciuto (Italy) and had a natural average dose of 133 ± 5 Gy ($n=14$) (publication in prep). The
46 feldspar samples SB36 and 44 were from the last glacial cycle and collected on Long-Island, NY. Sample SB36 had a
47 saturated pIR-IR₂₉₀ dose ($2D_0=328\pm 10$ Gy, $n=3$). Sample SB44 had an average pIR-IR₂₂₅ dose of 49 ± 1 Gy ($n=11$, not fading
48 corrected) and a pIR-IR₂₉₀ dose of 67 ± 3 Gy ($n=12$).

49 Coarse grain (180-250 μm) fractions were dispensed on 10-mm-diameter aluminium discs (quartz) and cups (feldspar) with a
50 silicone oil adhesive of 4-mm-diameter. Sixty aliquots per sample were prepared.

51 The luminescence measurements were performed on a Risø TL/OSL DA-20 reader equipped with a photomultiplier tube ET
52 PDM9107-CP-TTL and a $^{90}\text{Sr}/^{90}\text{Y}$ source delivering a dose of 0.106 ± 0.003 Gy. s^{-1} to the material deposited on a disc. The
53 luminescence signal from the quartz grains was stimulated with blue diodes emitting at 470 ± 30 nm and detected through a
54 combination of a 2.5- and 5-mm-thick Hoya U-340 glass filters (transmission between ~290–370 nm). The infrared stimulated
55 signal from the K-rich feldspar grains was stimulated with LEDs emitting at 850 ± 30 nm, and the luminescence signal was
56 detected through the so-called blue filter pack composed of a 3-mm-thick Schott BG3 and a 2-mm-thick Schott BG39 filter
57 (detection window centred on 410 nm).

58 A standard multi-grain Single-Aliquot Regenerative (SAR) procedure was used for the dose determination. After the
59 measurement of the natural OSL signal, the aliquots were subjected to regenerative-dose cycles (including a duplicate dose
60 and zero dose). The SAR protocol was applied to quartz samples with a preheat of 220°C for 10 s, and a cutheat of 180°C. The
61 quartz OSL signal was measured for 40 s at 125°C prior to heating at a higher temperature for the quartz samples. The net

62 intensity of the blue luminescence signal was integrated over the first 0.8 s after subtracting the background signal derived
63 from the last 8 s of stimulation. For feldspar, equivalent doses were measured using SAR protocols exploiting the IRSL signal
64 measured at low temperature and referred to as the IR₅₀ protocol (Huntley and Lamothe, 2001), as well as the post-infrared-
65 infrared luminescence signal measured at high temperature and referred to as the pIR-IR₂₉₀ (Thiel et al., 2011). Prior to the
66 IRSL stimulation, standard preheat conditions were applied at 250°C for 60 s and 320°C for 60 s, for the IR₅₀ and pIR-IR₂₉₀
67 protocols, respectively. Both luminescence signals were integrated over the first five seconds of stimulation, and the
68 background was taken from the last 10 s of stimulation. For quartz and feldspar samples, the growth curve was fitted with a
69 single saturating exponential function. The uncertainties on an individual dose have been determined using classical rules of
70 error combination using the Analyst software (Duller, 2007), a further systematic uncertainty of 2 % was added in quadrature
71 to each uncertainty value to account for calibration errors and machine reproducibility.

72 **3. Methodology**

73 **3.1 Lighting condition**

74 The decay of luminescence in both quartz and feldspar can be induced by any wavelength of solar radiation. More precisely,
75 the maximum bleaching rate of the quartz OSL signal is induced by short wavelength (in the UV-blue-green region), while
76 feldspar IRSL signals have their bleaching resonance in the long wavelengths (in the red-infrared region). Therefore, finding
77 an optimum lighting condition for both quartz and feldspar is difficult. Some luminescence laboratories use red bulbs or red
78 fluorescent tubes, which are particularly well adapted for quartz (Sutton and Zimmerman, 1978). Lamothe (1995) reports that
79 restriction to the wavelength region 650-600 nm can be obtained from a white fluorescent tube using three layers of Lee 106
80 filters (i.e., deep red) and an infrared trimming glass filter. However, Lindvall et al. (2017) reports a loss of 3 to 21% of the
81 quartz luminescence signal intensity after 24 h of exposure to the red wavelength. For feldspar, there is an optimum at 620-
82 540 nm in the yellow part of the spectrum (Huntley and Baril, 2002, their Fig.1). Orange-yellow wavelength can be obtained
83 using a low-pressure sodium vapor lamp with appropriate yellow filters to block the blue to ultraviolet emissions (Spooner,
84 1993, 2000). Sobhati et al. (2017, 2021) also observed that using amber light-emitting diodes (LEDs) with an emission peak
85 at 594 nm, quartz and feldspar lost only between 1 to 3 % of luminescence signal intensity after 48 h of exposure.

86 On another note, a comfortable laboratory illumination level is required for the safety of those spending long hours working
87 in the darkrooms. In low light conditions (e.g., moonless night), human eyes have a maximum sensitivity at 507 nm (in the
88 blue-green region), and red light is almost invisible. Green wavelength cannot be used in our laboratory as our lighting
89 environment, as it bleaches the quartz OSL signal. However, the closest solution and, therefore our best compromise is the
90 orange-yellow wavelength, similar to what was recommended by Sobhati et al. (2017, 2021).

91 **3.2 Bleaching test procedure**

92 All aliquots were bleached for five days in a solar simulator (UVACUBE400) equipped with a SOL500 lamp filtered with an
93 H1 filter glass (transmission range from 315 nm to 800 nm). Quartz samples received an artificial beta dose of 5 Gy (calibration
94 quartz) or 20 Gy (SB27). K-rich feldspar samples (SB36 and 44) received an artificial beta dose of 70 Gy. All the aliquots
95 were placed at different locations in the darkrooms for 24, 72, 240, and 720 h, and their remaining dose was measured and
96 normalized by the given dose. Noting that 720 h exposure is an unrealistic exposure time for sample preparation in the
97 laboratory, nevertheless, we wanted to investigate the effect of extremely long exposure.

98 To monitor the bleaching effect of the ceiling fixtures, the aliquots were placed on a benchtop at a workstation. To monitor the
99 bleaching effect of the dimmable LEDs, we fixed the light intensity at 20 % and 30 % of their maximum intensity inside our
100 two fume hoods with a black benchtop, and at 20 % inside our fume hood with a white benchtop.

101 In nature, the quartz OSL signal bleaches faster than the K-feldspar signals, and the K-feldspar IR₅₀ signal bleaches faster than
102 the K-feldspar pIR-IR₂₉₀ signal. Therefore, the OSL and IR₅₀ signals are key for monitoring the bleaching effect of our
103 laboratory darkroom lights, rather than the pIR-IR₂₉₀. The IR₅₀ signal is, however, and contrary to the pIR-IR₂₉₀ signal, affected
104 by anomalous fading, which is a loss of luminescence signal through time. To account for fading and overcome any laborious
105 fading correction, we measured all the aliquots 720 h after the initial beta irradiation. In practice, a set of aliquots was given a
106 dose of 70 Gy, and then stored in the dark for 720 h, while another set of aliquots was exposed to a light source for 24 h and
107 then stored in the dark for 696 h, while another set of aliquots was exposed for 72 h, and then stored in the dark for 648 h, and
108 so on. Assuming that all the aliquots are affected by the same fading rate after one month, any tendency that we will observe
109 as a result of our bleaching test is assumed to be the only effect of the light exposure.

110 4 Results

111 4.1 Spectral analysis

112 We measured the emission spectrum of three light sources: a red LED PAR38, a deep orange single LED, and a
113 dimmable deep orange LED stripline. Details on the LEDs are reported in Table 1. The PAR38 LED emits a peak wavelength
114 at ~600 nm (FWHM ~84 nm) with a large tail in both the short and the long wavelength emissions and a low-intensity peak at
115 ~452 nm, in the blue region of the spectrum (Fig. 1a). The single LED emits a peak wavelength of 594 nm and the stripline of
116 LEDs emits a peak wavelength at 596 nm (Fig. 1a). Both peaks are narrow with a FWHM of ~ 14 nm. Contrary to the red PAR
117 38 LED, the single and stripline LEDs results are the closest to our preferred conditions.

118

Figure 1: The normalized emission spectra of (a) the LED PAR38, single LED, and LED stripline, (a) the single LED through different long-pass filter combination, (c) the single LED through layers of the 158 Deep Orange LEE filter (LEE158), (d) the LED stripline through layers of the LEE158.

The single LED and the stripline LEDs have, however, a tail in the short wavelengths starting at ~530 nm in the green region of the spectrum. To reduce this short wavelength emission, we measured the emission spectrum of the single LED with

129 a series of long-pass filters: 106 primary red LEE, which has a cut-off at 580 nm, and 158 Deep Orange LEE, which has a cut-
130 off at 530 nm. As expected, the primary red filter successfully removed the short-wavelength emission (Fig. 1b), however, the
131 peak wavelength shifted from 594 nm to 597 nm, and a tail in the long wavelength emissions appeared (up to 640 nm). With
132 the orange filter, the tail in the short wavelengths is slightly reduced, while the rest of the LED emission spectrum remains the
133 same (Fig. 1b). Using both filters simultaneously results in an emission spectrum similar to the one obtained with the primary
134 red filter (Fig. 1b). In order to narrow the emission band of the single LED, we measured its spectrum with additional layers
135 of 158 Deep Orange LEE long-pass filter. Figure 1c shows that adding one, two, or three layers of orange filter significantly
136 contributes to reducing the short-wavelength emission while slightly increasing the long-wavelength emission. With three
137 layers of orange filter, the single LED peak wavelength is at 595 nm (FWHM ~13 nm). Similarly, adding three layers of 158
138 Deep Orange LEE long-pass filter in front of the stripline LEDs successfully removes the green emission (Fig. 1d), while the
139 peak emission remains at 596 nm (FWHM ~13 nm).

140 Our ceiling lighting consists of line track fixtures made of aluminium alloy placed at ~1.70 cm from the benchtop
141 (Fig. 2a). Each fixture has a single orange LED covered by three layers of 158 Deep Orange LEE filters and a transparent
142 acrylic glass (1-mm-thick). We checked that the transparent acrylic glass does not change the light spectrum. Inside the fume
143 hoods, we used the dimmable LED stripline covered by three layers of 158 Deep Orange LEE filters and a transparent
144 acrylic glass (3-mm-thick), placed at 1.20 cm from the benchtop (Fig. 2b-d). The same stripline of dimmable orange LEDs
145 with 158 Deep Orange LEE filters was fixed under the wall-mounted cabinets, and 0.50 cm from the benchtop.

146

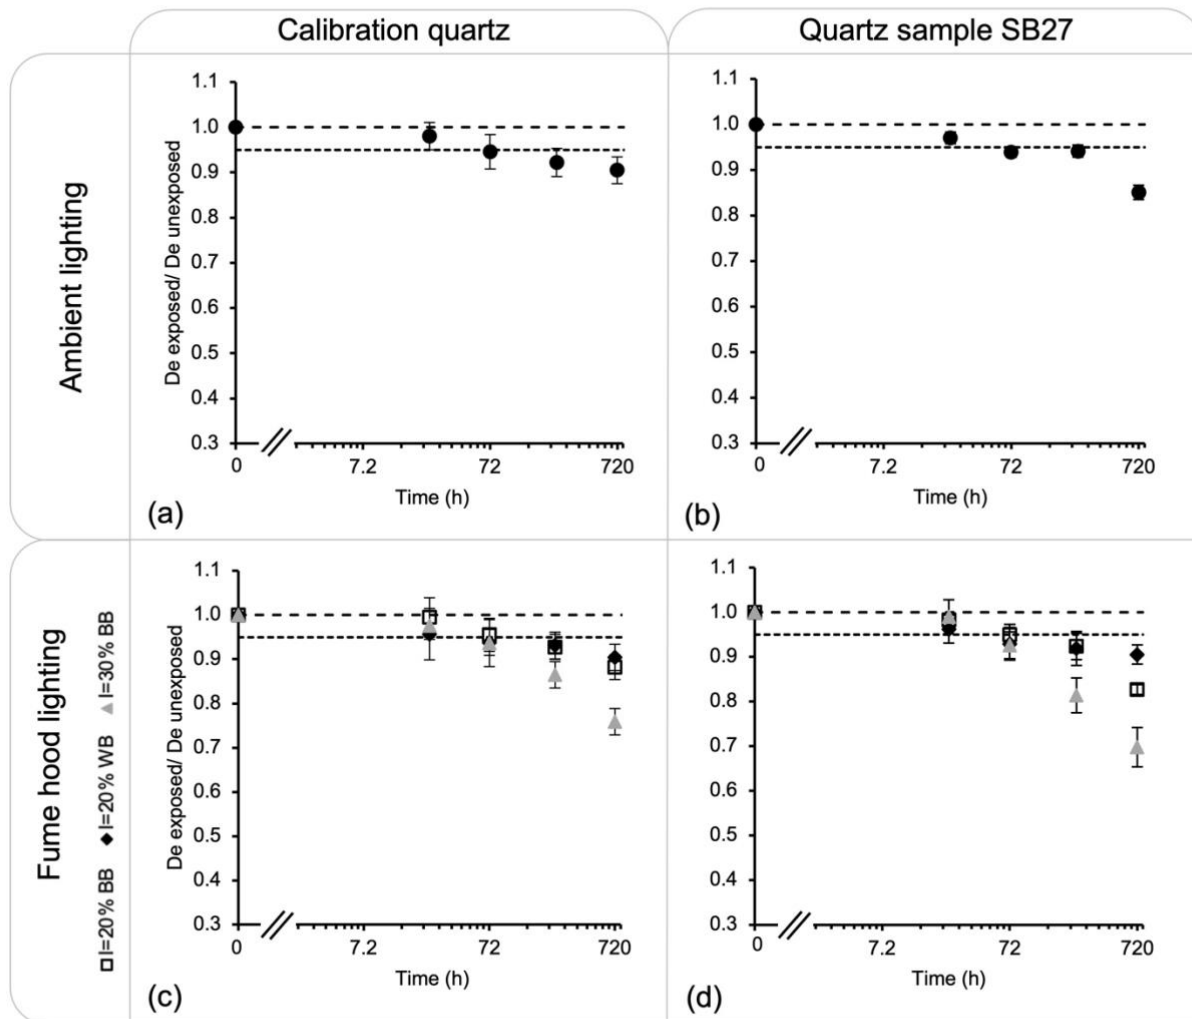

147 **Figure 2: Pictures of the laboratory setting in the laboratory darkroom showing the ceiling light fixture (a), and the fume hood**
148 **lighting (b-d).**

149 **4.2 Bleaching test**

150 Here we report on the capacity of our light sources in bleaching quartz and feldspar samples. Each ambient fixture
151 delivers 0.4 lux at the sample location on a benchtop. The intensity of the LED stripline in fume hood #1 was fixed at 20 %
152 and delivered 1.1 lux at the sample location on a white benchtop (referred to as I=20 % WB in Fig. 3). The intensity of the
153 LED stripline in fume hood #2 was fixed at 20 % and delivered 1.1 lux at the sample location on a black benchtop (referred
154 to as I=20 % BB in Fig. 3). The intensity of the LED stripline in fume hood #3 was fixed at 30 % and delivered 1.7 lux at the
155 sample location on a black benchtop (referred to as I=30 % BB in Fig. 3). These settings remained constant throughout the
156 experiment.

157 For all samples, we decided to report the results as dose loss because such value is directly comparable to the equivalent dose.
158 However, it is worth noting that the signal intensity loss was equal to or lower (within 2%) than the dose loss. Such a small
159 difference could be due to the fact that some aliquots were re-used multiple times over this experiment, which may have
160 affected the grain's sensitivity.

161

162

163

164

165

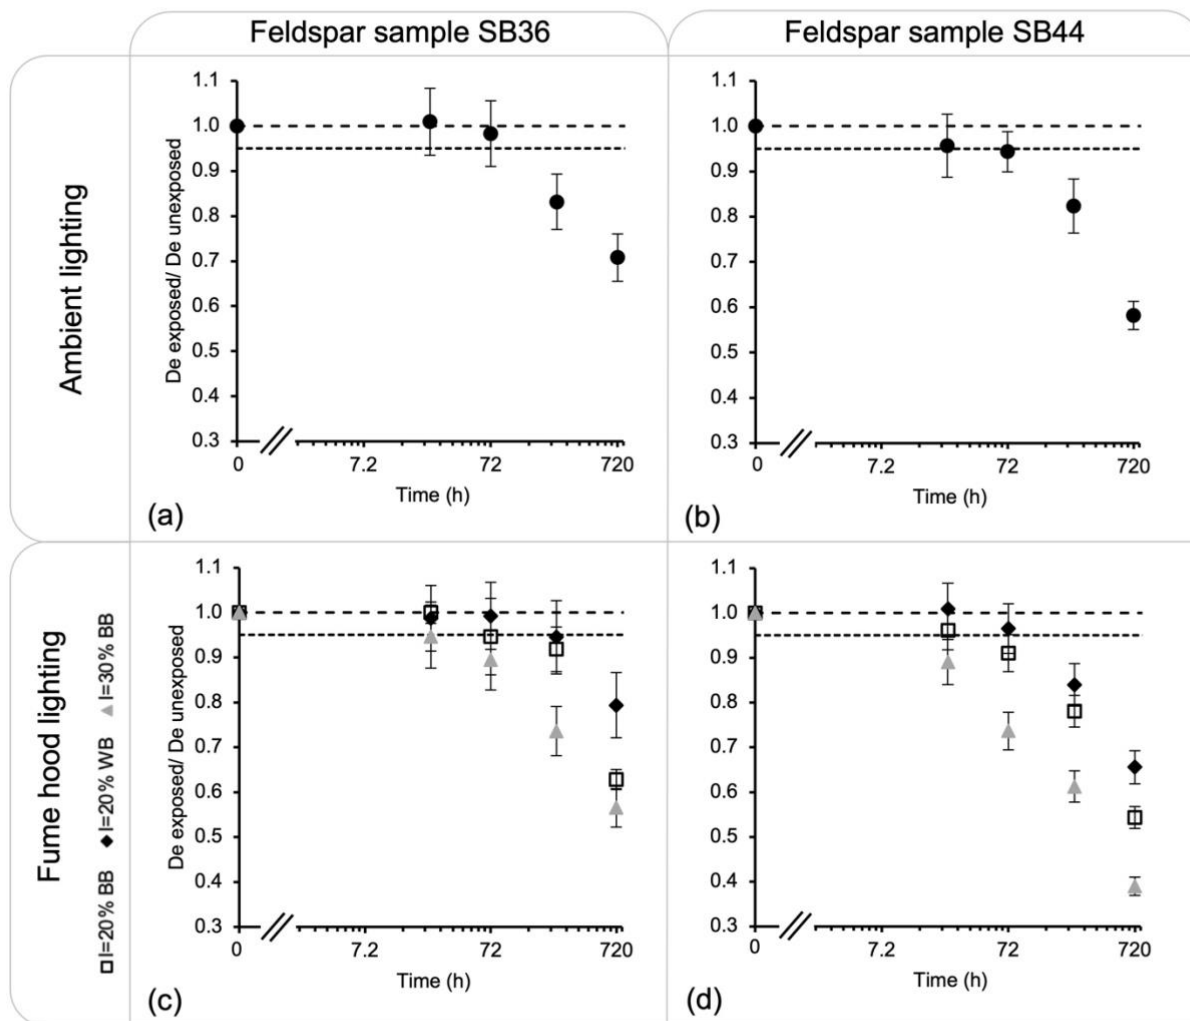

166

167

Figure 3: Ratio between the measured OSL dose from aliquots exposed to light and the measured dose from aliquots unexposed. The figures show the results from (a) the Risø calibration quartz exposed to the ceiling light fixture, (b) the quartz sample SB27 exposed to the ceiling light fixture, (c) the Risø calibration quartz exposed to fume hood lighting, and (d) the quartz sample SB27 exposed to fume hood lighting. Three aliquots were measured per exposure time. The long dashed line indicates a ratio of 1, and the dashed line indicates a loss of 5 %.

168 Figure 3a-b shows the dose decrease after exposure to the ceiling light fixture for the Risø calibration quartz and
169 sample SB27. Both samples displayed a ~3% (average) dose loss after 24 h and ~5 % after 72 h. After a substantially longer
170 exposure of 720 h, the Risø calibration quartz displayed a dose loss of ~10% and sample SB27 of ~18 %. Figure 3c-d shows
171 the remaining dose after exposure to the LED striplines within the fume hoods. For the Risø calibration quartz, the dose loss
172 is indistinguishable for the three settings after 24 h exposure. Beyond this time, however, the fume hood with the LED set to
173 an intensity of 30 % induced the fastest dose loss. The bleaching rates between the fume hood with the light intensity fixed at
174 20 % and the white benchtop or the black benchtop are indistinguishable. For both settings, the dose lost is ~1 % after 24 h
175 exposure and ~10 % after 720 h exposure. For quartz sample SB27, a similar tendency has been observed; a dose loss of ~1
176 % (average) has been recorded for the three settings after 24 h exposure. For the fume hoods with the light intensity fixed at
177 20 %, a ~10 % loss in dose was recorded after 240 h exposure, and up to 18 % after 720 h. The light fixed at 30 % intensity
178 provoked the fastest dose loss.

179 This set of measurements has been repeated on two K-rich feldspar samples. The results show more dispersion in the measured
180 dose, possibly due to the anomalous fading (all aliquots were stored and/or exposed for 30 days before measurement). Figure
181 4a-b illustrates the remaining dose after exposure to the ceiling light fixture. Before 72 h of exposure, the dose loss less than
182 ~5 % for both samples, while after 72 h, there is a drastic decrease in dose for both samples. After 720 h exposure, the dose
183 loss is between 30 to 40%.

184
 185 **Figure 4: Ratio between the measured IR₅₀ dose from aliquots exposed to light and the measured dose from aliquots unexposed.**
 186 **The figures show the results from (a) the feldspar sample SB36 exposed to the ceiling light fixture, (b) the feldspar sample SB44**
 187 **exposed to the ceiling light fixture, (c) the feldspar sample SB36 exposed to fume hood lighting, and (d) the feldspar sample SB44**
 188 **exposed to fume hood lighting. Three aliquots were measured per exposure time. The long dashed line indicates a ratio of 1, and**
 189 **the dashed line indicates a loss of 5 %.**

190 Figure 4c-d shows the remaining dose of the initial given dose after exposure to the LED striplines within the fume
191 hoods. The LED's set to an intensity of 30 % displayed the most rapid dose loss. After 24 h of exposure, both samples lost
192 between 5 to 10% dose, and up to ~40 to 60 % after 720 h exposure. For the settings set at 20 % intensity, there was no loss
193 dose recorded for sample SB36, after 24 h of exposure. The dose loss remains less than 5 % after 72 h of exposure and less
194 than 10% after 240 h. After 720 h of exposure, the dose loss ranges between 20 to 40 %. For sample SB 44 (Fig 4d), the
195 aliquots exposed to the LED stripline with an intensity of 30 % had a ~10 % dose loss after 24 h, and ~60 % dose loss after
196 720 h of exposure. For the aliquots placed under the fume hoods with an LED intensity of 20%, the dose loss was up to 5%
197 after 24 h, 10 % after 72 h, and between 30 to 40 % after 720 h. Overall, sample SB44 bleaches faster than sample SB36. A
198 difference in bleaching response from different K-rich feldspar samples has been observed by Sohbaty et al., (2017) and
199 interpreted as due to variation in the grain's optical transmission.

200 This experiment has been repeated to measure the bleaching effect of each setting on the pIR-IR₂₉₀ dose of the same
201 K-feldspar samples (SB36 and SB44) for up to 72 h of exposure. The measured doses are undistinguishable from the given
202 dose at 1 sigma, and therefore indicate no measurable bleaching effects of our light sources on the pIR-IR₂₉₀ dose.

203 Our results show the same tendency as the results reported by others (e.g., Bailif and Poolton, 1991; Spooner, 1993,
204 1994a, b, 2000; Sohbaty et al., 2017). K-rich feldspar IRSL signal decay faster than the quartz OSL signal when exposed to
205 yellow-orange light. The reason for such difference is, however, not fully understood. Additional analyses on well-
206 characterized samples from different origins would be required to understand the relationship between bleaching rate and
207 geochemical composition.

208 **5 Conclusion**

209 Two lighting settings have been implemented in the new Luminescence Dating Research Laboratory at Stony Brook
210 University. For ambient lighting, ceiling fixtures were equipped with single orange LEDs. For task-oriented lighting, a
211 dimmable orange LED stripline was mounted below the wall-mounted cabinets and inside the fume hoods. Both settings are
212 covered with three layers of 158 Deep Orange LEE filters, and their peak wavelength is at 595 nm and 596 nm, respectively.
213 Our bleaching tests quantified the dose loss in quartz and K-rich feldspar samples with exposure. The ambient lighting
214 delivering 0.4 lux at the sample position induced a loss of less than 3 % in the quartz OSL dose after 24 h of exposure and
215 between 0 to 5 % in the K-rich feldspar IR₅₀ doses, with no effect on their pIR-IR₂₉₀ dose. The fume hood lighting at an
216 intensity of 20 %, delivering 1.1 lux at the sample position, induced a loss of less than 5 % in quartz OSL and K-rich feldspar
217 IR₅₀ dose after 24 h of exposure. At an intensity of 30 %, the stripline of LEDs induced more rapid bleaching. Therefore, we
218 recommend using the dimmable orange LED stripline at more than 20% intensity only in case of emergency or during lab
219 cleaning.

220 Our setting is well adapted to luminescence dating darkrooms by providing a comfortable laboratory illumination for the
221 operator, which has a minimal bleaching effect on the samples. During laboratory preparation, the samples are exposed to

222 ambient lighting only for a few hours, mainly during sieving and density separation, and to the fume hood lighting for a few
223 minutes when pouring chemicals. The total light exposure to darkroom lighting should be less than 24h. In addition, extreme
224 precautions should be taken at each step to avoid unnecessary light exposure by using non-transparent beakers when possible,
225 covering the sample container with an opaque lid or aluminium foil, switching off the light in the fume hood when sample
226 manipulation is not necessary, and storing the sample in an opaque container while preparing the aliquots. Finally, we plan on
227 monitoring regularly the bleaching effect of our light sources as we work on samples from various origins.
228

229 **Code/Data availability:** All data are available upon request.

230 **Author contribution:** MF designed the experiments, and TG carried them out. WH and OE built the light ceiling fixture. MF
231 designed and built the LED striplines.

232 **Competing interests:** We declare no competing interests

233 **Acknowledgments:** MF would like to thank Desmond DeLanty (architect) for designing the ceiling fixtures and installing the
234 light sources in the laboratory.

264

265 **Short summary.** Here, we present the lighting setting implemented in the new Luminescence Dating Research Laboratory at
266 Stony Brook University, USA. First, we performed spectral measurements on different light sources and filters. Then, we
267 measured the loss of dose in quartz and feldspar samples when exposed to various light sources and durations. Finally, we
268 conclude that our lighting setting is suitable for a luminescence darkroom laboratory, it is simple, inexpensive to build, and
269 durable.
