Abstract. We present a deep learning approach based on the physics-informed neural networks (PINNs) for estimating thermal evolution of the crust during tectonic uplift with a changing landscape. The approach approximates the temperature field of the crust with a deep neural network, which is trained by optimizing the heat advection-diffusion equation under boundary conditions such as initial and final thermal structure, topographic history, and surface and basal temperatures. From the trained neural network of temperature field and the prescribed velocity field, one can predict the temperature history of a given rock particle that can be used to compute the cooling ages of thermochronology. For the inverse problem, the forward model can be combined with a global optimization algorithm that minimizes the misfit between predicted and observed thermochronological data, in order to constrain unknown parameters in the uplift history or boundary conditions. We demonstrate the approach with solutions of one- and three-dimensional forward and inverse models of the crustal thermal evolution, which are consistent with results of the finite-element method. The three-dimensional model simulates the post-orogenic topographic decay of the Dabie Shan, China, with constraints from fission-track and (U-Th)/He ages.

1 Introduction

Thermochronology has been used extensively in earth sciences for quantifying ages and rates of geological and landscape evolution processes. To interpret the data, thermal structure of the crust must be understood. In the thermochronology community, analytical and finite-element methods have been used to estimate the temperature field, under either steady-state conditions or time-varying topography.

Recently, the deep learning method of physics-informed neural networks (PINNs) was proposed for solving partial differential equations, and its application has been demonstrated in many research fields including earth sciences. With rapidly increasing computing power, the method offers a valuable alternative to traditional analytical and numerical methods, with great potential to improve with the fast-evolving machine learning algorithm.

Here we demonstrate that PINNs can be used to solve the heat transfer equation in the crust for given uplift and landscape histories. Examples shown in this paper are implemented using the TensorFlow 2 library, with great flexibility to be adapted for complex boundary conditions.

2 From thermochronological ages to exhumation rates: existing methods

25 In this section we provide a brief overview of the widely used methods for interpretation of thermochronological data, highlighting in particular how they deal with the subsurface thermal field and its influence on the observed data.

2.1 Age-elevation relationship and thermal history modeling

Some conventional methods interpret thermochronological data without considering the thermal structure in the crust. The age-elevation relationship is an approach in low-temperature thermochronology for estimating the rock exhumation rates (e.g., Fitzgerald et al., 1995; Fitzgerald and Malusà, 2019), based on the variation of apparent ages between samples from different elevations. The method adopts the concept of “closure temperature” (Dodson, 1973), which considers the cooling age of a sample to reflect the time when it passed through a certain temperature. To estimate the exhumation rate, the method assumes that the closure temperature of a thermochronometer had remained at the same depth in the crust. Therefore, as rocks of different elevations, from higher to lower, should have passed the closure depth (i.e., depth of the closure temperature isotherm) consecutively, a positive correlation between the samples’ cooling ages and elevations is expected. As a change in the exhumation rate can perturb the isotherms, leading to a transient state of the thermal field, the age-elevation relationship approach is only reliable when the exhumational steady state is achieved for a given thermochronometer (Willett and Brandon, 2002). In the case of steady state, cooling ages and elevations of samples from a topographic relief should yield a linear relationship whose slope is the exhumation rate for the period indicated by the thermochronological ages.

40 The age-elevation relationship can be interpreted in combination with thermal history modeling (e.g., Ketcham, 2005; Gallagher, 2012). The modeling predicts thermochronological ages for a given time-temperature path based on kinetic models of fission-track annealing or noble gas diffusion; the forward model is often used together with an optimization method (e.g., a Monte Carlo method) in order to estimate the optimal (“best-fit”) thermal history for an observed dataset of thermochronology. For example, by assigning a temporally varying temperature offset between samples from different elevations, one can simultaneously optimize the time-temperature paths of rock samples on a (near-)vertical profile as well as the history of the temperature offset. Assuming that the elevation offset between samples on the profile has remained constant, the optimal temperature offset history can be used to provide constraints on the evolution of the paleo-geothermal gradient (e.g., Jiao et al., 2014; Jepson et al., 2022). Then the exhumation rates can be derived from the modeled thermal history and geothermal gradient. This approach requires no assumption of a steady-state or monotonic cooling history. However, at any time in the parameter space the modeling procedure uses linear interpolation to determine the temperatures of samples according to their positions on the profile, which is not consistent with the crustal thermal profile in the case of rapid exhumation.

2.2 Solving the subsurface thermal field

To ensure that the estimated exhumation rate is consistent with the physics of heat transfer, the thermal structure of the crust can be solved using analytical methods or numerical models in one, two, or three dimensions.

55 To elucidate the exhumation of the Olympic Mountains on the Cascadia Margin, Brandon et al. (1998) designed an approach to compute the apatite fission-track age for one-dimensional (1D) steady-state exhumation. For a given exhumation rate, the approach uses an analytical approximation (Stüwe et al., 1994) of the heat advection-diffusion equation to solve the thermal profile of the crust, which is then used to find the exhumation rate and the closure temperature (dependent on cooling rate; Dodson, 1973) through a numerical iteration. By using different kinetic parameters for track annealing or noble gas diffusion in
60 the closure temperature equation, this approach has been updated to estimate exhumation rates from various thermochronometers (Reiners et al., 2003; Van Der Beek and Schildgen, 2023). To avoid the assumption of a steady-state scenario, Willett and Brandon (2013) proposed an alternative approach to solve the thermal profile of earth over a half-space domain, which requires constraints on the final geothermal gradient to quantify the transience of the thermal profile.

To solve the 1D heat transfer problem, the methods mentioned above all assume a constant exhumation rate for the time
65 period from the date indicated by the cooling age of thermochronology to the present-day. Fox et al. (2014) developed a linear inversion method to infer the variation of exhumation rates in time and space. To estimate the temporal variation of rates, the method also uses a 1D thermal model and the Dodson (1973)'s approximation but considers the closure depth as a summation of rates over a finite number of time intervals. This discretization leads to more unknown parameters (i.e., exhumation rates) than data (i.e., cooling ages) and is thus an underdetermined problem. Therefore, the solution of the problem through linear
70 inversion relies on some independent knowledge of the unknowns (e.g., *a priori* mean exhumation rate and the variance on this mean) to construct the covariance matrix of the exhumation rates. In the covariance matrix, Fox et al. (2014) also introduces a spatial correlation function in order to smooth the exhumation rates in space.

The 1D thermal models ignore the heat transport in horizontal directions. To capture the perturbation of isotherms by surface topography, instead of a sample's true elevation the mean elevation filtered by the wavelength of topography (Stüwe et al., 1994;
75 Mancktelow and Grasemann, 1997) has been used in the 1D models for solving the thermal profile of the crust (Brandon et al., 1998; Willett and Brandon, 2013; Fox et al., 2014; Van Der Beek and Schildgen, 2023). Two-dimensional (2D) numerical modeling has also been used to solve the temperature fields under undulating topography during exhumation. Mancktelow and Grasemann (1997) used a 2D finite-difference method to compute the transient isotherms to assess the influence of topography and uplift on estimated exhumation rates in active orogens. To constrain the exhumation pattern and history of the central
80 Wasatch Mountains using thermochronological data, Ehlers et al. (2003) coupled a 2D velocity field and a thermal model to compute the temperature field evolution in the mountains; the thermal model is solved using a finite-difference method. To simulate the temperature field around hydrothermal systems, Luijendijk (2019) published a model to solve the subsurface heat flow in the 2D sections using the finite-element method, which have been used to predict apatite fission-track and (U-Th)/He data.

85 For simulating the three-dimensional (3D) crustal thermal field evolution, PECUBE (Braun, 2003; Braun et al., 2012) has been the only computer code widely used in the low-temperature thermochronology community. This finite-element code solves the 3D heat transfer equation in the crust under a prescribed velocity field and evolving topography, and uses the solution to compute temperature histories of rocks as well as ages of various thermochronometers. The forward modeling is often combined with the Neighborhood Algorithm (Sambridge, 1999a, b), an optimization method, to search for best-fit values

90 of the parameters used to define the input scenarios (i.e., tectonic or geomorphic) by iteratively minimizing the misfit between the predicted and observed data.

3 Physics-informed neural networks

The physics-informed neural network (PINN) was recently proposed to solve forward and inverse problems involving partial differential equations (PDEs) (Raissi et al., 2019). In the context of PINNs, a fully-connected neural network is generally employed to approximate the solution of the PDEs, e.g., the temperature, $T(z, t)$, by taking the spatial and temporal coordinates (z and t) as the inputs. As demonstrated in Figure 1, the neural network is composed of multiple hidden layers with trainable parameters and nonlinear activation functions. The parameters in the network can be learned using a loss function based on the governing equations (i.e., PDEs) and the boundary and initial conditions of the PDEs. For inverse problems, we add a misfit term representing the difference between the network output and the observation; two separate optimizers are used for the loss function and data misfit. In following sections we will demonstrate the networks case by case using numerical experiments.

A key procedure in PINNs is to compute the derivatives of the PDEs. To address this issue, PINNs use automatic differentiation (AD) to represent all differential operators that exist in the PDEs. The AD calculates the derivatives of the outputs with respect to the network inputs based on the chain rule, which is different from numerical computations and avoids discretization and truncation errors. After training with the loss function (and data misfit), the trained network can be used to approximate the solution of PDEs at any location and any time.

PINNs have been applied in various disciplines such as fluid mechanics (Cai et al., 2021a; Raissi et al., 2020; Boster et al., 2023), and have demonstrated great potential in solving governing equations of physical laws in complex domains, especially in solving inverse problems. They have also attracted attention in the community of Earth sciences. For examples, Waheed et al. (2021) used PINNs to solve the eikonal equation in 2D for predicting traveltimes of seismic waves in isotropic and anisotropic media. He and Tartakovsky (2021) used PINNs to solve the advection-dispersion and Darcy flow equations in 1D and 2D fields with spatially varying hydraulic conductivity. Rasht-Behesht et al. (2022) used PINNs to solve the acoustic wave propagation and full waveform inversions under different and complex boundary conditions.

4 One-dimensional thermal profile: a synthetic model

4.1 Forward solution

115 The 1D heat advection-diffusion equation to solve is given by

$$\frac{\partial T}{\partial t} + u \frac{\partial T}{\partial z} - \kappa \frac{\partial^2 T}{\partial z^2} = 0, \quad (1)$$

where T is the temperature ($^{\circ}\text{C}$), t is the time (Ma), u is the rock uplift rate (km/Myr), κ is the thermal diffusivity here set at $25 \text{ km}^2/\text{Myr}$, and z is the vertical position (km) relative to the model base ($z = 0$). In this model we assume no topographic

change over time, so u is equal to the exhumation rate. We solve the model in the space defined by

$$120 \quad t \in [0, 50] \quad \text{and} \quad z \in [0, 20], \quad (2)$$

for which Dirichlet boundary conditions are imposed as

$$T(t, 0) = 500 \quad \text{and} \quad T(t, 20) = 0, \quad (3)$$

with a linear gradient prescribed for the initial condition, i.e.,

$$T(0, z) = 500 - 25z. \quad (4)$$

125 We assume that u is time-dependent and impose its time dependence in terms of a logistic function as

$$u(t) = u_0 + \frac{\Delta u_1}{1 + e^{-(t-t_1)/\Delta t}}, \quad (5)$$

in which $u_0 = 0.05$ km/Myr, $\Delta u_1 = 0.6$ km/Myr, $t_1 = 30$ Ma, and $\Delta t = 1$ Ma. Overall, the forward model describes the thermal profile evolution of a 20 km-thick crust from 0 to 50 Ma, with the surface and basal temperatures fixed at 0 and 500°C, respectively. The model uplift rate remained constant at 0.05 km/Myr from 0 to about 30 Ma, after which it increased by 0.6 to

130 0.65 km/Myr; Δt is an inertia factor that imposes a time length for transition between the two uplift rates (Figure 2a).

To solve the forward model, we approximate T as a deep neural network (DNN), and such that $T(t, z)$ can be learned by minimizing the loss function

$$\mathcal{L} = \mathcal{L}_f + \alpha \mathcal{L}_b, \quad (6)$$

where \mathcal{L}_f penalizes the residual of the governing equations (i.e., PDEs) and \mathcal{L}_b imposes the boundary conditions and initial conditions of the PDEs; α is a weighting parameter which we set to 1 for all experiments shown in this paper. Here the initial condition is considered as a special boundary condition. \mathcal{L}_f and \mathcal{L}_b are computed by

$$\mathcal{L}_f = \frac{1}{N_f} \sum_{i=1}^{N_f} |f(t_f^i, z_f^i)|^2, \quad (7)$$

$$\mathcal{L}_b = \frac{1}{N_b} \sum_{i=1}^{N_b} |T_b^i - T(t_b^i, z_b^i)|^2, \quad (8)$$

140 in which $f(t, z)$ is defined for the left-hand side of the heat transfer equation (Equation 1), $\{t_f^i, z_f^i\}_i^{N_f}$ depict the N_f collocation points for $f(t, z)$, and $\{t_b^i, z_b^i\}_i^{N_b}$ depict the N_b initial and boundary training data on $T(t, z)$.

In our demonstration, we use the TensorFlow 2 library (Abadi et al., 2015) to build the DNN, which includes three hidden layers with 20 neurons in each layer and an additional transform layer to impose the boundary conditions as hard constraints (Lagaris et al., 1998; Lu et al., 2021). The hyperbolic tangent function (*tanh*) is used as the activation function, and the *Adam* optimizer algorithm (Kingma and Ba, 2014) is used for minimizing the loss function (Equation 6). The model is set up with

145 1000 randomly sampled collocation points, and 150 points for the initial and boundary conditions (50 for the initial geotherms, 50 for the surface temperature, and 50 for the basal temperature)(Figure 2b).

The solution presented here was optimized through 8,000 iterations with a constant learning rate of 0.001. In the first 5,000 iterations, the model loss \mathcal{L} has decreased rapidly from $>100,000$ to <10 (Figure 3). After that, \mathcal{L} becomes more stable and is only reduced by 3 for the next 3,000 iterations. Figure 4 shows the thermal profiles at different model times predicted by the
150 DNN at various stages of the training, in comparison with the solution of the finite-element method (FEM) which used 101 points on the profile and a time step of 0.5 Ma. To compare the final solutions of the PINN and FEM, we compute the square and infinity norms of the misfits between the predictions of the two as

$$l^2 = \sqrt{\sum_{i=1}^n \epsilon_i^2}, \quad (9)$$

$$l^\infty = \max(|\epsilon_i|), \quad (10)$$

155 in which ϵ_i is the difference in temperatures predicted by the PINN and FEM at locations of each element and n is the number of elements used in FEM, i.e., 101 in this example. At model times of 5, 10, 25, and 50 Ma, l^2 are calculated at 30, 16, 40, and 45 °C, and l^∞ at 4, 2, 5, and 8 °C, indicating reasonable consistence between the solutions of the two methods (Figure 4). To test the influence on the thermochronological data, we also computed ages of different methods for the rock sample ending at the surface. The sample's thermal history (Figure 5a) is calculated from the trained DNN and the input uplift
160 function (Figure 2a). Based on the extracted time-temperature path, thermochronological ages are computed using an empirical model of the fission-track annealing (Ketcham et al., 2007) and the noble gas diffusion kinetics (summarized by Reiners and Brandon, 2006) solved by a finite-difference method (Braun et al., 2006). As a result, ages computed from thermal histories predicted by the PINN and FEM show good consistency (Figure 5b), with l^2 and l^∞ of the computed age differences at 1.3 and 0.8 Ma, respectively.

165 4.2 Inverse problem

We transform the forward model to an inverse problem by considering u_0 , Δu_1 , and t_1 in the uplift function (Equation 5) as unknown parameters. All other parameters defining the thermal model remain as the same as in the forward problem (Section 4.1). Implementation of the DNN follows a similar setup as that of a forward model, except that the three unknown parameters are updated and optimized during the iterations by reducing the misfit between predicted and observed ages. The
170 age misfit function is defined by

$$\text{Misfit} = \frac{1}{N_a} \sum_{i=1}^{N_a} \left(\frac{p_i - o_i}{\sigma_i} \right)^2, \quad (11)$$

where p_i is the predicted age, o_i is the observed age, σ_i is the uncertainty on the observation, and N_a is the total number of observed ages. For the problem demonstrated here, synthetic age data predicted from the temperature history computed using

the FEM (Figure 5) are used as data, and a 10% uncertainty (standard deviation) is assumed for each data point. For calculation
175 of the synthetic observed data, 0.05 km/Myr, 0.6 /km/Myr, and 30 Ma, are used as “true” values of u_0 , Δu_1 , and t_1 in the uplift
function (Equation 5), respectively.

While the *Adam* algorithm is used for fitting $\{t_f^i, z_f^i\}_i^{N_f}$ for loss functions from the physical law and boundary conditions,
to avoid local minima the search for optimal values of the unknown parameters in the uplift function is conducted using a
stochastic, derivative-free approach, i.e., the differential evolution (DE) algorithm (Storn and Price, 1997) implemented in the
180 SciPy library (Virtanen et al., 2020). DE maintains a population of candidate solutions and improves them iteratively according
to a measure of the solution quality (e.g., a misfit function). The optimization procedure is not based on the gradient of the
forward model, and is therefore suitable for solving multidimensional inverse problems that are non-differentiable, noisy, or
variable through time. DE initializes the solution population by generating a set of random candidate solutions within the
predefined space. During the optimization, for each base solution in the candidate population, a muted solution is created by
185 adding a weighted difference between two other random candidate solutions from the population to a third random one. The
muted solution is then mixed with the base solution to create a crossover solution. The crossover and its corresponding base
solution are compared, and only the one with a better quality (i.e., a lower misfit) is selected and kept in the population of
candidate solutions. The mutation, crossover, and selection steps constitute a generation of DE, which is repeated many times
to explore the parameter space to seek for optimal solutions with the highest quality.

190 Different strategies can be used for the initialization, mutation, and crossover steps of DE. For models presented in this
paper, a quasi-random population is initiated using a Sobol sequence and updated using the “*best2bin*” strategy, in which the
mutation and crossover are based on the currently best solution, two differential variants, and a binomial experiment (Storn
and Price, 1997). Both differential weight and crossover constant are set to fixed values, both at 0.5. We combine *Adam* and
DE by applying them at different frequencies: the optimization of the inverse problem contains n_g generations of DE with
195 a population size of n_p , and each candidate solution of the forward model is assessed every n_a number of *Adam* iterations.
We tested the optimization performance with different configuration of n_g (120, 240, 100), n_p (128, 64, 32), and n_a (10, 10,
50), with all configurations resulting in a total of $\sim 160,000$ iterations. The learning rate for *Adam* is set at 0.001 for the first
100,000 iterations and lowered to 0.0001 for the rest of training. We restrict the searches of u_0 , Δu_1 , and t_1 within ranges of
0–2 km/Myr, 0–2 km/Myr, and 0–50 Ma, respectively.

200 The optimization performances are shown as evolution of the loss from physical law and boundary conditions (Figure 6a)
and misfits between the predicted and observed thermochronological data (Figure 6b). For different combining configurations
of *Adam* and DE, the parameter sampling performances are presented in Figure 7. For all three configurations tested, searches
of the unknown parameters yield reasonable convergence towards the true values. The results also demonstrate that a larger
population size of DE leads to better exploration of the parameter space (Figures 7a-c) whereas a higher value of n_a may help
205 increase the efficiency of convergence (Figure 7g-i).

Figure 8 shows the “best-fit” models in the final generations of DE for the three runs, which yield the lowest misfits to the
age data. These models can reproduce the synthetic cooling ages of the six thermochronometers, with l^2 and l^∞ in the ranges
of 1.1–1.5 Ma and 0.9–1.4 Ma, respectively. The “best-fit” models predict uplift and thermal histories very consistent with the

“true” model for the fast uplift period, but less accurate for the slow period, suggesting possible less constraints of the data for
210 the older part of the history.

5 Three-dimensional temperature field: post-orogenic decay of the Dabie Shan

In this section, we use an example from the Dabie Shan, eastern China (Figuer 9), to demonstrate the application of PINNs
for solving the 3D temperature field under changing topography. The Dabie Shan is a Mesozoic mountain range which has
undergone slow exhumation and topographic decay since the Late Cretaceous (Reiners et al., 2003; Braun and Robert, 2005).

215 5.1 Forward solution

Assuming that the rock motion is in the vertical direction, the 3D heat transfer equation is given by

$$\frac{\partial T}{\partial t} + u \frac{\partial T}{\partial z} - \kappa \left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} \right) = 0, \quad (12)$$

where x , y , and z are spatial coordinates and other parameters are the same as in Equation 1. We focus on the low-temperature
and post-orogenic exhumation history of the mountain and solve its thermal history since 150 Ma. The model space is defined
220 as

$$t \in [0, 150], \quad x \in [0, 159], \quad y \in [0, 199], \quad \text{and} \quad z \in [0, 36.5], \quad (13)$$

in which the z domain includes a crustal thickness ($h_c = 30$ km) below sea level and the surface elevation of the mountain range
(h_s). Temperature at the model base is fixed at 600°C. The earth surface temperature is set at 15°C at sea level and calibrated
according to the elevation using an atmospheric lapse rate at $-5^\circ\text{C}/\text{km}$. Therefore, the boundary conditions are imposed as

$$225 \quad T(t, x, y, 0) = 600 \quad \text{and} \quad T(t, x, y, z_s(t, x, y)) = 15 - 5h_s(t, x, y), \quad (14)$$

in which z_s and h_s are the vertical coordinate and surface elevation, respectively, with a relationship

$$z_s = h_s + 30. \quad (15)$$

We follow Braun and Robert (2005) and simulate the surface relief change by modifying the amplitude of topography, such
that

$$230 \quad h_s(t, x, y) = w(t)h_s(0, x, y), \quad (16)$$

in which w is a time-dependent amplification factor for topography (Figure 10b), prescribed by

$$w(t) = \begin{cases} w_0, & t \in [0, t_d] \\ 1 + (w_0 - 1) \frac{150 - t}{150 - t_d}, & t \in (t_d, 150] \end{cases} \quad (17)$$

where w_0 , set at 4, is the amplification of topography at the beginning of model ($t = 0$) and t_d , set at 70 Ma, is the model time when the post-orogenic decay of the topography starts. The present-day topography ($h_s(0, x, y)$) is extracted from the global elevation model (GEBCO 2014) and resampled to 2 km resolution. Equation 17 describes a scenario in which between 150 and 80 Ma ago (i.e., model time from 0 to 70 Ma) the surface relief was four times as high as that of today, and after 80 Ma the topography has gradually decreased in a linear fashion towards the current level.

The initial thermal field is imposed using a linear interpolation of temperatures between the model base and earth surface, i.e.,

$$240 \quad T(0, x, y, z) = T(0, x, y, 0) - \frac{T(0, x, y, 0) - T(0, x, y, z_s(0, x, y))}{z_s(0, x, y)} z. \quad (18)$$

Based on conclusions of Reiners et al. (2003) and Braun and Robert (2005), we assume a spatially uniform uplift model and define it using a piecewise function (Figure 10a),

$$u(t) = \begin{cases} u_0, & t \in [0, t_1] \\ u_1, & t \in (t_1, 150], \end{cases} \quad (19)$$

where $u_0 = 0.6$ km/Myr, $u_1 = 0.05$ km/Myr, and $t_1 = 40$ Ma. Therefore, on geological time, the rock uplift remained constant at 0.6 km/Myr between 150 and 110 Ma, and then the rate decreased to 0.05 km/Myr and remained constant until the present-day.

Similar to the solution of the 1D model, we approximate T as a DNN and train it using the same loss function (Equation 6). The loss functions from 3D heat transfer law and boundary (and initial) conditions become

$$\mathcal{L}_f = \frac{1}{N_f} \sum_{i=1}^{N_f} |f(t_f^i, x_f^i, y_f^i, z_f^i)|^2, \quad (20)$$

$$250 \quad \mathcal{L}_b = \frac{1}{N_b} \sum_{i=1}^{N_b} |T_b^i - T(t_b^i, x_b^i, y_b^i, z_b^i)|^2, \quad (21)$$

in which $f(t, x, y, z)$ stands for the left-hand side of the 3D heat transfer equation (Equation 12).

The DNN used for the 3D model consists of six hidden layers with 20 neurons on each and an additional layer to transform the outputs. The activation function, optimizer, and learning rate all remain the same as for the 1D model. To impose the initial and boundary conditions, we select 2,000 random points to set up the initial thermal field ($t = 0$; Figure 11a), whereas 2,000 and 5,000 randomly sampled points are used to represent the temperatures at the model base ($z = 0$) and on the surface topography ($z = z_s$), respectively (Figure 11b). We set up the model with 50,000 collocation points (Figure 11c), with half of them allocated randomly within the orogenic phase ($t \in [0, 40]$) and the other half post-orogenic ($t \in (40, 150]$).

The model is optimized through 100,000 iterations with learning rates of 0.01 and 0.001 for the first 20,000 and the rest iterations, respectively. Figure 12 shows the performance of the optimization. To verify the accuracy of the solution of the PINN, we also computed the thermal field evolution of the Dabie Shan using a FEM code, i.e., PECUBE (Braun, 2003). The FEM model is set up on a $120 \times 120 \times 31$ ($x \times y \times z$) grid, and the heat transfer is solved at a time step of 1 Myr. The uplift history

and boundary conditions are set up as the same as in the PINN model. Figure 13 compares the temperature profiles on three transects across the model at 40 and 150 Ma (model time) solved by the the PINN and FEM. On each transect at 40 Ma, the l^2 and l^∞ of the misfits between the temperatures predicted by the two methods are in the ranges of 238–324 °C and 20–40 °C, respectively, which are calculated at locations of 3100 elements; at 150 Ma when the topographic relief is lower, the two norms are reduced to 66–92 °C and 8–10 °C, respectively.

We also extracted thermal histories for all rock points that ended at the present-day surface and computed apatite fission-track and (U-Th)/He ages. The calculated ages based on the solutions from the PINN and FEM yield consistent patterns both in the map area (Figure 14) and on the elevation profiles (Figure 15). The l^2 and l^∞ norms for the AFT age misfits predicted by the PINN and FEM, which are calculated using 42,000 surface samples, are 943 and 17 Ma, respectively; the two norms for AHe age misfits of the two methods are 424 and 12 Ma, respectively.

5.2 Inverse problem

We test the capability of PINNs in solving an inverse problem with real data. To define the problem, we set the onset time and rate of the post-orogenic uplift (t_1 and u_1 in Equation 19) and the initial topographic amplification (w_0 in Equation 17) as unknown parameters. The three parameters are sampled in the ranges of 0–100 Ma, 0–0.1 km/Myr, and 0–6, respectively. To limit the number of dimensions for inversion, we keep the uplift rate during the orogenic phase (u_0) and the time of topographic decay (t_d) as fixed. Thermochronological age data reported by Reiners et al. (2003)(Figure 9b) are used to guide the optimization; only ages <150 Ma are used. Similar to the inversion of the 1D model, *Adam* and DE are combined for optimization. The inversion result presented here is based on 200 generations of DE with a population size of 32, and each generation of DE contains 50 iterations of *Adam*. A total of 320,000 iterations were run.

As a comparison, we also searched the multi-dimensional space defined by the unknown parameters using the Neighborhood Algorithm (NA) (Sambridge, 1999a), in which the forward model is solved using PECUBE (Braun, 2003). The NA partitioned the parameter space into Voronoi cells, and during each iteration the method evaluates the model misfit according to the parameter values at the center of each cell. Then for the next iteration, new samples will be generated within a subset of cells which contain the best-fitting models from the previous step. This process is repeated many times in order to find the optimal values of the unknown parameters that can reproduce the observed data. Here our NA search contains a total of 26 iterations, with 300 forward models in the first iteration and 60 in each of the rest. After evaluating all models in each step, out of the 60 cells we resample 50 with the best-fitting models to generate new combinations of parameter values for the next iteration.

Performance of the optimization of the PINN is shown in Figure 16, and sampled parameters are shown in Figure 17. It appears that estimates of u_1 and t_1 using DE converge quickly to ranges of 0.04–0.06 km/Myr and 35–70 Ma (Figure 17a-b), respectively, whereas that of w_0 to >4 after 125 generations of DE (200,000 forward models; Figure 17c). These ranges are in general consistency with the results of the NA search (Figure 17). However, while parameter search using NA can converge continuously and eventually to a relatively narrow range, it appears that sampling using DE may reach a stable population and stop converging. Further evaluation of the optimization performance requires estimates of the probability functions of the sampled values, which will be a direction for the future development (Section 6.2).

The results of our inverse modeling are in general consistency with tBraun and Robert (2005)'s conclusions based on inversion of the same dataset, which suggested that during the post-orogenic evolution since the Late Cretaceous, the Dabie Shan experienced slow uplift at 0.01–0.04 km/Myr and a topographic decay by a factor of 2.5 to 4.5. It is worth noting that the uplift in our model combines the background rock uplift and the isostatic compensation whereas Braun and Robert (2005)'s model accounted for the two separately, and thus it is reasonable for our estimates of the uplift rate and the magnitude of erosion-induced topographic decay to be higher.

6 Discussion

6.1 Advantage of PINNs

We have shown that PINNs can be applied in the study of thermochronology, to solve heat transfer in the crust for providing constraints on the uplift and exhumation processes of the crust. Our examples demonstrate that, built on the machine learning frameworks such as the TensorFlow and PyTorch, solutions of forward and inverse problems of crustal heat transfer are straightforward. The implementation is flexible and similar for both the forward and inverse problems, making it easy to impose and modify boundary conditions based on various assumptions and observations, such as topographic history, geothermal fields, and thermochronological data. Compared to the data assimilation methods which may require expansive computations for an inverse problem, PINNs may be more efficient as the method solves the equations in one training process. In addition, PINNs can seamlessly integrate different kinds of experimental data (e.g., temperature data and velocity data) with the governing equations, making it possible to integrate multi-fidelity data in real experiments (Meng and Karniadakis, 2020).

6.2 Current limitations and future directions

Our examples show that, at least for a relatively simple time-space domain, a basic configuration of the optimization (e.g., *tanh* activation function, *Adam* optimizer, constant or piecewise learning rate, etc.) on a CPU platform can lead to efficient training of PINNs. However, we expect that for more complex domains that require a higher density of collocation points, better strategies may be required for training the models. On the one hand, it is an ongoing effort to improve the algorithm and setup for efficient optimization of PINNs (Jagtap et al., 2020). On the other hand, implementation of the PINNs on a multi-GPU cluster is a viable approach to increase the computation efficiency for larger problems (Shukla et al., 2021).

Our demonstrations have only considered the uplift history as space-independent rates in the vertical direction. Previous work (e.g., Cai et al., 2021b) has shown that implementation of a full 3D velocity field in the neural networks is possible. However, in cases with sharp changes in the velocity fields, the capability and efficiency of PINNs to solve PDEs remain to be tested or improved (e.g., Rasht-Behesht et al., 2022). This is crucial for tectonic studies in which the exhumation and geothermal patterns have been perturbed by fault activities, and therefore should be a focus of future development of the method.

Our current solution of the inverse problem includes a final solution of the heat model with values of unknown parameters. Although the direct search process (i.e., DE) results in an ensemble of sampled parameter values, they are not appraised

to quantify the uncertainties of the optimized parameters. To add estimates of the parameter uncertainties, one can employ a Bayesian neural network, where the parameters in the neural network follow Gaussian distributions, instead of a fully-connected network where the parameters are all deterministic in the PINNs framework (Yang et al., 2021). By doing this, the
330 Bayesian PINNs can adapt to noisy data and provide estimates of the uncertainties for the inferred parameters in the PDEs.

Code availability. Codes for examples shown in the paper, implemented using the TensorFlow 2 library, are available from https://github.com/jjaor/PINNs_Chron/.

Data availability. Apatite and zircon (U-Th)/He and apatite fission-track ages from the Dabie Shan were published by Reiners et al. (2003).

Author contributions. RJ conceived the idea, developed the code, carried out the tests. SC tested the codes. All authors wrote the manuscript
335 together.

Competing interests. The authors have declared no competing interests.

Acknowledgements. RJ's research is supported by the Natural Sciences and Engineering Research Council of Canada (Discovery Grant 2019-04405). We thank Stan Dosso for his feedback on the manuscript.
